
A philosophical and mathematical dictionary

Charles Hutton

A

PHILOSOPHICAL AND MATHEMATICAL

DICTIONARY.

VOL. II.

PRINTED BY S. HAMILTON,
Weybridge, Surrey.

A

PHILOSOPHICAL AND MATHEMATICAL

DICTIONARY:

CONTAINING

AN EXPLANATION OF THE TERMS, AND AN ACCOUNT OF THE SEVERAL SUBJECTS,

COMPRISED UNDER THE HEADS

MATHEMATICS, ASTRONOMY, AND PHILOSOPHY

BOTH NATURAL AND EXPERIMENTAL;

WITH AN

HISTORICAL ACCOUNT OF THE RISE, PROGRESS, AND PRESENT STATE OF THESE SCIENCES:

ALSO

MEMOIRS OF THE LIVES AND WRITINGS OF THE MOST EMINENT AUTHORS,

BOTH ANCIENT AND MODERN,

WHO BY THEIR DISCOVERIES OR IMPROVEMENTS HAVE CONTRIBUTED TO THE ADVANCEMENT OF THEM.

BY CHARLES HUTTON, LL.D.

FELLOW OF THE ROYAL SOCIETIES OF LONDON AND EDINBURGH, AND OF THE PHILOSOPHICAL SOCIETIES OF HAARLEM AND AMERICA; AND EMERITUS PROFESSOR OF MATHEMATICS IN THE ROYAL MILITARY ACADEMY, WOOLWICH.

IN TWO VOLUMES:

WITH MANY CUTS AND COPPER-PLATES.

A NEW EDITION,

WITH NUMEROUS ADDITIONS AND IMPROVEMENTS.

VOL. II.

LONDON:

PRINTED FOR THE AUTHOR;

F. C. AND J. RIVINGTON; J. CUTHELL; LAW AND WHITTAKER; LONGMAN, HURST, REES, ORME, AND BROWN; CADELL AND DAVIES; J. MAWMAN; BLACK, PARRY, AND CO; BALDWIN, CRADOCK AND JOY; J. BOOKER; G. AND S. ROBINSON; T. HAMILTON; WALKER AND EDWARDS; JOHN ROBINSON; B. REYNOLDS; AND SIMPKIN AND MARSHALL.

1815.

A

PHILOSOPHICAL AND MATHEMATICAL DICTIONARY.

M.

M, In Astronomical Tables, &c, is used for meridional or southern; and sometimes for meridian, or mid-day.—In the Roman numeration, it denotes a thousand.

MACHIN (JOHN), a very distinguished mathematician, was some time professor of astronomy at Gresham-college, (to which he was elected May 16, 1713, on the resignation of Dr. Torriano,) and secretary of the Royal Society, died June 9, 1751. His papers in the Philos. Trans. were, 1. To find the curve which a descending body describes in the shortest time, vol. 30; 2. On a Distempered Skin, vol. 37; 3. A Solution of Kepler's Problem. Besides these, by an approximating series of Dr. Halley's, Mr. Machin computed the circumference of the circle to 100 places of figures. And another ingenious approximating series of his own is given in Mr. Jones's Synopsis Palmariorum Matheseos, 1706, the investigation of which was first given in Dr. Hutton's Mensuration, 1772. Mr. Machin's Laws of the Moon's Motion were printed in Motte's translation of Newton's Principia.

MACHINE, denotes any thing that serves to augment, or to regulate moving powers: or it is any body destined to produce motion, so as to save either time or force. The word, in Greek, signifies an invention, or art: and hence, in strictness, a machine is something that consists more in art and invention, than in the strength and solidity of the materials; for which reason it is that the inventors of machines are called Ingenieurs, or Engineers.

Machines are either simple or compound. The simple machines are the 6 mechanical powers, viz, the lever, pulley, wheel-and-axle, inclined plane, wedge, and screw; which are otherwise called the simple mechanic powers. The balance also is a lever.

These simple machines serve for different purposes, according to their different structures; and it is the business of the skilful mechanist to choose and combine them, in the manner that may be best adapted to produce the desired effect. The lever is a very useful machine for many purposes, its power being readily varied as the occasion may require; when weights are to be raised only a little way, such as stones out of quarries, &c. On the other hand, the wheel-and-axle serves to raise weights from the greatest depth, or to the greatest height. Pulleys, being easily carried, are therefore much employed in ships. The balance is useful for ascertaining an equality of weight. The wedge is very useful for separating the parts of bodies; and being impelled by the force of percussion, it is incomparably greater than any of the other powers. The screw is useful for compressing or squeezing bodies together, and also for raising very heavy weights to a small height; its great friction is even of considerable use, to preserve the effect already produced by the machine.

Compound MACHINE, is formed from these simple machines, combined together for different purposes. The number of compound machines is almost infinite; and yet it would seem that the ancients went far beyond the moderns in the powers and effects of them; especially their machines of war and architecture.

Accurate descriptions and drawings of machines would be a very curious and useful work. But to make a collection of this kind as beneficial as possible, it should contain also an analysis of them; pointing out their advantages and disadvantages, with the reasons of the constructions; also the general problems implied in these constructions, with their solutions &c, should be noticed. Though a complete work of this kind be still wanting, yet many curious and useful particulars may be gathered from Strada, Besson, Beroaldus, Augustinus de Ramellis, Bockler, Leupold, Beyer, Limpergh, Van Zyl, Perault, and others; a short account of whose works may be found in Wolfii Commentatio de Præcipuis Scriptis Mathematicis; Elem. Mathes. Univ. tom. 5, pa. 84. To these may be added, Belidor's Architecture Hydraulique, Desaguliers's Course of Experimental Philosophy, Emerson's Mechanics, and Dr. Gregory's Mechanics, which contains a description of a great number of the most useful and modern machines. The Royal Academy of Sciences at Paris have also given a collection of machines and inventions approved of by them. This work, published by M. Gallon, consists of 6 vols. in 4to, containing engraved draughts of the machines, with their descriptions annexed.

MACHINE, *Architectonical*, is an assemblage of pieces of wood so disposed as that, by means of ropes and pulleys, a small number of men may raise great loads, and lay them in their places; such as cranes, &c.—It is hard to conceive what sort of machines the ancients must have used to raise those immense stones found in some of the antique buildings; as some of those still found in the walls of Balbeck in Turkey, the ancient Heliopolis, which are 63 feet long, 12 feet broad, and 12 feet thick, and which must weigh 6 or 7 hundred tons a-piece.

Blowing MACHINE. See BELLOWS.

Boylean MACHINE. Mr. Boyle's *Air-Pump.*

Electrical MACHINE. See ELECTRICAL *Machine.*

Wind MACHINE. See ANEMOMETER, and WIND *Machine.*

Hydraulic or *Water* MACHINE, is used either to denote a simple machine, serving to conduct or raise water, as a sluice, pump, and the like; or several of these acting together, to produce some extraordinary effect; as the

MACHINE *of Marli.* See FIRE-*engine*, STEAM-*engine*, and WATER-*works.*

Military MACHINES, among the ancients, were of three kinds: the first serving to throw arrows, as the scorpion; or javelins, as the catapult; or stones, as the balista; or fiery darts, as the pyrabolus: the 2d kind serving to beat down walls, as the battering-ram and terebra: and the 3d sort to shelter those who approach the enemy's wall, as the tortoise or testudo, the vinea, and the towers of wood. See the respective articles.

The machines of war now in use, consist in artillery, including cannon, mortars, petards, &c.

MACLAURIN (COLIN), a very eminent mathematician and philosopher, was the son of a clergyman, and born at Kilmoddan in Scotland, in the year 1698. He was sent to the university of Glasgow in 1709; where he continued 5 years, applying to his studies in a very intense manner, and particularly to the mathematics. His great genius for mathematical learning discovered itself so early as at 12 years of age; when, having accidentally met with a copy of Euclid's Elements in a friend's chamber, he became in a few days master of the first 6 books without any assistance: and it is certain, that in his 16th year he had invented many of the propositions which were afterwards published as part of his work, entitled Geometria Organica. In his 15th year he took the degree of master of arts; on which occasion he composed and publicly defended a thesis on the power of gravity, with great applause. After this he quitted the university, and retired to a country-seat of his uncle, who had the care of his education, his parents having died while he was very young. Here he spent two or three years in pursuing his favourite studies; but in 1717, at 19 years of age only, he offered himself a candidate for the professorship of mathematics in the Marischal College of Aberdeen, and obtained it after a ten days trial, against a very able competitor.

In 1719, Mr. Maclaurin visited London, where he left his Geometria Organica to print, and where he became acquainted with Dr. Hoadley then bishop of Bangor, Dr. Clarke, Sir Isaac Newton, and other eminent men; at which time also he was admitted a member of the Royal Society: and in another journey, in 1721, he contracted an intimacy with Martin Folkes, esq. the president of it, which continued during his life.

In 1722, Lord Polwarth, plenipotentiary of the king of Great Britain at the congress of Cambray, engaged Maclaurin to go as a tutor and companion to his eldest son, who was then to set out on his travels. After a short stay at Paris, and visiting other towns in France, they fixed in Lorrain; where he wrote his piece, On the Percussion of Bodies, which gained him the prize of the Royal Academy of Sciences for the year 1724. But his pupil dying soon after at Montpelier, he returned immediately to his profession at Aberdeen. He was hardly settled here, when he received an invitation to Edinburgh; the curators of that university being desirous that he should supply the place of Mr. James Gregory, whose great age and infirmities had rendered him incapable of teaching. He had here some difficulties to encounter, arising from competitors, who had good interest with the patrons of the university, and also from the want of an additional fund for the new professor; which however at length were all surmounted, principally through the means of Sir Isaac Newton. Accordingly, in Nov. 1725, he was introduced into the university; after which the mathematical classes soon became very numerous, there being generally upwards of 100 students attending his lectures every year; who being of different standings and proficiency, he was obliged to divide them into four or five classes, in each of which he employed a full hour every day from the first of November to the first of June. In the first class he taught the first 6 books of Euclid's Elements, Plane Trigonometry, Practical Geometry, the Elements of Fortification, and an Introduction to Algebra. The second class studied Algebra, with the 11th and 12th books of Euclid, Spherical Trigonometry, Conic Sections, and the general Principles of Astronomy. The third studied Astronomy and Perspective, and read a part of Newton's Principia, he having performed a course of experiments for illustrating them: he afterwards read and demonstrated the Elements of Fluxions. Those in the fourth class read a System of Fluxions, the Doctrine of Chances, and the remainder of Newton's Principia.

In 1734, Dr. Berkeley, bishop of Cloyne, published a piece called the Analyst; in which he took occasion, from some disputes that had arisen concerning the grounds of the fluxionary method, to explode the method itself; and also to charge mathematicians in general with infidelity in religion. Maclaurin thought himself included in this charge, and began an answer to Berkeley's book: but other answers coming out, and as he proceeded, so many discoveries, so many new theories and problems occurred to him, that instead of a vindicatory pamphlet, he produced a Complete System of Fluxions, with their application to the most considerable problems in Geometry and Natural Philosophy. This work was published at Edinburgh in 1742, 2 vols. 4to; and as it cost him infinite pains, so it is the most considerable of all his works, and will do him immortal honour, being indeed the most complete treatise on that science that has yet appeared.

In the mean time, he was continually presenting the public with some observation or performance of his own, several of which were published in the 5th and 6th volumes of the Medical Essays at Edinburgh. Many of them were likewise published in the Philosophical Transactions; as the following: 1. On the Construction and Measure of Curves, vol. 30.—2. A New Method of describing all kinds of Curves, vol. 30.—3. On Equations with Impossible Roots, vol. 34.—4. On the Roots of Equations, &c, vol. 34.—5. On the Description of Curve Lines, vol. 39.—6. Continuation of the same, vol. 39.—7. Observations on a Solar Eclipse, vol. 40.—8. A Rule for finding the Meridional Parts of a Spheroid with the same Exactness as in a Sphere, vol. 41.—9. An Account of the Treatise of Fluxions, vol. 42.—10. On the Bases of the Cells where the Bees deposit their Honey, vol. 42.

In the midst of these studies, he was always ready to lend his assistance in contriving and promoting any scheme which might contribute to the public service. When the earl of Morton went, in 1739, to visit his estates in Orkney and Shetland, he requested Mr. Maclaurin to assist him in settling the geography of those countries, which was very erroneous in all the maps; to examine their natural history, to survey the coasts, and to take the measure of a degree of the meridian. Maclaurin's family affairs would not permit him to comply with this request: he however drew up a memorial of what he thought necessary to be observed, and furnished proper instruments for the work, recommending Mr. Short, the celebrated optician, as a proper operator for the management of them.

Mr. Maclaurin had still another scheme for the improvement of geography and navigation, of a more extensive nature; which was the opening a passage from Greenland to the South Sea by the north pole. That such a passage might be found, he was so fully persuaded, that he used to say, if his situation could admit of such adventures, he would undertake the voyage, even at his own charge. But when schemes for finding it were laid before the parliament in 1741, and he was consulted by several persons of high rank concerning them, and before he could finish the memorials he proposed to send, the premium was limited to the discovery of a north-west passage: he regretted much that the word west was inserted, because he thought that passage, if at all to be found, must lie not far from the pole.

In 1745, having been very active in fortifying the city of Edinburgh against the rebel army, he was obliged to fly from thence into England, where he was invited by Dr. Herring, archbishop of York, to reside with him during his stay in this country. In this expedition however, being exposed to cold and hardships, and naturally of a weak and tender constitution, which had been much more enfeebled by close application to study, he laid the foundation of an illness which put an end to his life, in June 1746, at 48 years of age, leaving his widow with two sons and three daughters.

Mr. Maclaurin was a very good, as well as a very great man, and worthy of love as well as admiration. His peculiar merit as a philosopher was, that all his studies were accommodated to general utility; and we find, in many places of his works, an application even of the most abstruse theories, to the perfecting of mechanical arts. For the same purpose, he had resolved to compose a course of Practical Mathematics, and to rescue several useful branches of the science from the ill treatment they often met with in less skilful hands. These intentions however were prevented by his death; unless we may reckon, as a part of his intended work, the translation of Dr. David Gregory's Practical Geometry, which he revised, and published with additions, in 1745.

In his lifetime, however, he had frequent opportunities of serving his friends and his country by his great talents. Whatever difficulty occurred concerning the constructing or perfecting of machines, the working of mines, the improving of manufactures, the conveying of water, or the execution of any public work, he was always ready to resolve it. He was employed to terminate some disputes of consequence that had arisen at Glasgow, concerning the gauging of vessels; and for that purpose presented to the commissioners of the excise two elaborate memorials, with their demonstrations, containing rules by which the officers now act. He made also calculations relating to the provision, now established by law, for the children and widows of the Scotch clergy, and of the professors in the universities, entitling them to certain annuities and sums, on the voluntary annual payment of a certain sum by the incumbent. In contriving and adjusting this wise and useful scheme, he bestowed a great deal of labour, and contributed not a little towards bringing it to perfection.

Of his works, we have mentioned his Geometria Organica, in which he treats of the description of curve lines by continued motion; as also of his piece which gained the prize of the Royal Academy of Sciences in 1724. In 1740, he likewise shared the prize of the same academy, with the celebrated D. Bernoulli and Euler, for resolving the problem relating to the motion of the tides from the theory of gravity: a question which had been given out the former year, without receiving any solution. He had only 10 days to draw this paper up, and could not find leisure to transcribe a fair copy; so that the Paris edition of it is incorrect. He afterwards revised the whole, and inserted it in his Treatise of Fluxions; as he did also the substance of the former piece. These, with the Treatise of Fluxions, and the pieces printed in the Medical Essays and the Philosophical Transactions, a list of which is given above, are all the writings which our author lived to publish. Since his death, however, two more volumes have appeared; his Algebra, and his Account of Sir Isaac Newton's Philosophical Discoveries. The Algebra, though not finished by himself, is yet allowed to be excellent in its kind; containing, in a moderate volume, a complete elementary treatise on that science, as far as it had then been carried; besides some neat analytical papers on curve lines. His Account of Newton's Philosophy was occasioned in the following manner:—Sir Isaac dying in the beginning of 1728, his nephew, Mr. Conduitt, proposed to publish an account of his life, and desired Mr. Maclaurin's assistance. The latter, out of gratitude to his great benefactor, cheerfully undertook, and soon finished the History of the Progress which Philosophy had made before Newton's time; and this was the first draught of the work in hand; which not going forward, on account of Mr. Conduitt's death, was returned to Mr. Maclaurin. To this he afterwards made great additions, and left it in the state in which it now appears. His main design seems to have been, to explain only those parts of Newton's Philosophy, which have been controverted; and this is supposed to be the reason why his grand discoveries concerning light and colours are but transiently and generally touched upon; for it is known, that whenever the experiments, on which his doctrine of light and colours is founded, had been repeated with due care, this doctrine had not been contested; while his accounting for the celestial motions, and the other great appearances of nature, from gravity, had been misunderstood, and even attempted to be ridiculed.

MACULÆ, in Astronomy, are dark spots appearing on the luminous surfaces of the sun and moon, and even some of the planets. The solar maculæ are dark spots of an irregular and changeable figure, observed in the face of the sun. These are said to have been first observed in November and December of the year 1610, by Galileo in Italy, and Harriot in England, unknown to, and independent of each other, soon after the invention of telescopes. But Montucla, in his History of the Mathematics, says that the honour of this discovery is due to J. Fabricius, as appears from his work published at Wittenberg, in June 1611, entitled, De Maculis in Sole visis, et earum cum sole revolutione narratio. They were afterwards also observed by Scheiner, Hevelius, Flamsteed, Cassini, Kirch, and others. See MACULÆ, NEBULOUS, SPOTS, &c.

MADRIER, in Artillery, is a thick plank, armed with plates of iron, and having a cavity sufficient to receive the mouth of a petard, with which it is applied against a gate, or any thing else intended to be broken down.—This term is also applied to certain flat beams, fixed to the bottom of a moat, to support a wall.—There are also madriers lined with tin, and covered with earth; serving as defences against artificial fires, in lodgments, &c, where there is need of being covered overhead.

MÆSTLIN (MICHAEL), in Latin Mæstlinus, a noted astronomer of Germany, was born in the duchy of Wittemberg; but spent his youth in Italy, where he made a speech in favour of Copernicus's system, which brought Galileo over from Aristotle and Ptolemy, to whom he was before wholly devoted. He afterwards returned to Germany, and became professor of mathematics at Tubingen; where, among his other scholars, he taught the celebrated Kepler, who has commended several of his ingenious inventions, in his Astronomia Optica. Mæstlin published many mathematical and astronomical works, and died in 1590.—Though Tycho Brahé did not assent to Mæstlin's opinion, yet he allowed him to be an extraordinary person, and deeply skilled in the science of astronomy.

MAGAZINE, a place in which stores are kept, of arms, ammunition, provisions, &c.

Artillery MAGAZINE, or the magazine to a field battery, is made about 25 or 30 yards behind the battery, towards the parallels, and at least 3 feet under ground, to receive the powder, loaded shells, port-fires, &c.—Its roof and sides should be well secured with boards, to prevent the earth from falling in: it has a door, and a double trench or passage sunk from the magazine to the battery, the one to enter, and the other to go out at, to prevent confusion. Sometimes traverses are made in the passages, to prevent ricochet shot from entering the magazine.

Powder-MAGAZINE, is the place where powder is kept in large quantities. Authors differ very much with regard to the situation and construction of these magazines; but all agree, that they ought to be arched and bomb-proof. In fortifications, they were formerly placed in the rampart; but of late they have been built in different parts of the town. The first powder-magazines were made with Gothic arches: but M. Vauban thinking these too weak, constructed them of a semicircular form, the dimensions being 60 feet long within, and 25 feet broad; the foundations are 8 or 9 feet thick, and 8 feet high from the foundation to the spring of the arch; also the floor 2 feet from the ground, to preserve it from the damp.

It is a constant observation, that after the centering of semicircular arches is struck, they settle at the crown, and rise up at the hances, even with a straight horizontal extrados; and still more so in powder-magazines, where the outside at top is formed, like the roof of a house, by inclined planes joining in an angle over the top of the arch, to give a proper descent to the rain; which effects are exactly what might be expected from the true theory of arches. Now, this shrinking of the arches, as it must be attended with very bad consequences, by breaking the texture of the cement, after it has in some degree been dried, and also by opening the joints of the vousoirs at one end, I have provided a remedy for this inconvenience, with regard to bridges, by the arch of equilibration, in my Tracts, vol. 1: but as the ill consequences of it are much greater in powder-magazines, in question 96 of my Mathematical Miscellany, I proposed to find an arch of equilibration for them also; which question was there resolved by Mr. Wildbore and myself, both upon general principles, and which I illustrated by an application to a particular case, there constructed, and accompanied with a table of numbers for that purpose. From that solution it appears that the general value of the ordinate PC or y, is $y =$

$$b \times \frac{\log. \frac{w + \sqrt{(w^2 - a^2)}}{a}}{\log. \frac{c + \sqrt{(c^2 - a^2)}}{a}};$$

where (in the following figure) $y = $ PC, $a = $ KD, $b = $ AQ $= \frac{1}{2}$ AB, $c = $ AL, and $w = $ IC; from which equation PC may be found, when IC is given. But if, on the other hand, PC be given, to find IC, which will be the more convenient way, then from the former equation will be found,

$w = \frac{a^2 + n^2}{2n} = $ CI; where $n = 2\cdot718281828$ the number whose hyp. log. is $cy + $ A, and A $=$ log. of a, also C $= \frac{1}{b} \times$ log. of $\frac{c + \sqrt{(c^2 - a^2)}}{a}$. Thus for example, in the following figure, representing a transverse vertical section of the arch, if the span AB $= 20$, the pitch or height DQ $= 10$, the thickness at top DK $= 7$, and the angle at top LKM $= 112° 37'$; then for every different value of PC, the last equation will give the following correspondent values of CI. That is, if ALKMB represent a vertical transverse section of the arch, the roof forming an angle LKM of $112° 37'$, also PC an ordinate parallel to the horizon taken in any part, and IC perpendicular to the same, and the other dimensions as above; then for properly constructing the curve so as to be the strongest, or an arch of equilibration in all its parts, the corresponding values of PC and CI will be as in the following table, where those numbers may denote any lengths whatever, either inches, or feet, or half-yards.

Value of CP.	Value of CI.

See my Tracts, vol. 1, pa. 57 &c.

MAGAZINE, or *Powder-Room*, on ship-board, is a close room or store-house, built in the fore or after part of the hold, in order to preserve the gunpowder for the use of the ship. This apartment is strongly secured against fire, and no person is allowed to enter it with a lamp or candle; it is therefore lighted, as occasion requires, by means of the candles or lamps in the light-room contiguous to it.

MAGELLANIC CLOUDS, whitish appearances like clouds, seen in the heavens towards the south pole, and having the same apparent motion as the stars. They are three in number, two of them near each other.—The largest lies far from the south pole; but the other two are not many degrees more remote from it than the nearest conspicuous star, that is, about 11 degrees. Mr. Boyle conjectures that if these clouds were seen through a good telescope, they would appear to be multitudes of small stars, like the milky way. Dr. Herschel thinks rather that nebulæ are often owing to a self-luminous fluid. See Philos. Trans. an. 1791, pa. 71, and an. 1811, pa. 269.

MAGIC LANTERN, an optical machine, by means of which small painted images are represented on the wall of a dark room, magnified to any size at pleasure. This machine was contrived by Kircher (see his Ars Magna Lucis et Umbræ, pa. 768); and it was so called, because the images were made to represent strange phantasms, and terrible apparitions, which have been taken for the effect of magic, by such as were ignorant of the secret.

This machine is composed of a concave speculum, from 4 to 12 inches diameter, reflecting the light of a candle through the small hole of a tube, at the end of which is fixed a double convex lens of about 3 inches focus. Between the two are successively placed, many small plain glasses, painted with various figures, usually such as are the most formidable and terrifying to the spectators, when represented at large on the opposite wall.

Thus (pl. 17, fig. 14) ABCD is a common tin lantern, to which is added a tube FG to draw out. In H is fixed the metallic concave speculum, from 4 to 12 inches diameter; or else, instead of it, near the extremity of the tube, there must be placed a convex lens, consisting of a segment of a small sphere, of but a few inches in diameter. The use of this lens is to throw a strong light upon the image; and sometimes a concave speculum is used with the lens, to render the image still more vivid. In the focus of the concave speculum or lens, is placed the lamp L; and within the tube, where it is soldered to the side of the lantern, is placed a small lens, convex on both sides, being a portion of a small sphere, having its focus about the distance of 3 inches. The extreme part of the tube FM is square, and has an aperture quite through, so as to receive an oblong frame NO passing into it; in which frame there are round holes, of an inch or two in diameter. Answering to the magnitude of these holes there are circles drawn on a plain thin glass; and in these circles are painted any figures, or images, at pleasure, with transparent water-colours. These images fitted into the frame, in an inverted position, at a small distance from the focus of the lens I, will be projected on an opposite white wall of a dark room, in all their colours, greatly magnified, and in an erect position. By having the instrument so contrived, that the lens I may move on a slide, the focus may be made, and consequently the image appear distinct, at almost any distance.

Or thus: Every thing being managed as in the former case, into the sliding tube FG, insert another convex lens K, the segment of a sphere rather larger than I. Now, if the picture be brought nearer to I than the distance of the focus, diverging rays will be propagated as if they proceeded from the object; therefore, if the lens K be so placed, as that the object be very near its focus, the image will be exhibited on the wall, greatly magnified.

MAGIC *Square*, is a square figure, formed of a series of numbers in arithmetical progression, so disposed in parallel and equal ranks, as that the sums of each row, taken either perpendicularly, horizontally, or diagonally, are equal to one another. As the following square, formed of these nine numbers, 1, 2, 3, 4, 5, 6, 7, 8, 9, where the sum of the three figures in every row, in all the directions, is always the same number, viz 15. But if the same numbers be placed in their natural order, in form of a square, the first being 1, and the last of them a square number, they will form what is called a natural square, whose two diagonals, as also its middle column, and middle horizontal line, will have the same sum as all the rows of the magic square, viz. 15.

Natural Square.

1	2	3
4	5	6
7	8	9

Magic Square.

3	5	7
8	1	6

Or in the two following squares of the first 25 numbers,

Natural Square.

1	2	3	4	5
6	7	8	9	10
11	12	13	14	15
16	17	18	19	20
21	22	23	24	25

Magic Square.

16	14	8	2	25
3	22	20	11	9
15	6	4	23	17
24	18	12	10	1
7	5	21	19	13

where every row and diagonal in the magic square makes just the sum 65, being the same as the two diagonals of the natural square, as well as of the middle row and middle column.

It is probable that these magic squares were so called both because of this property in them, viz, that the ranks in every direction making the same sum, appeared extremely surprising, especially in the more ignorant ages, when mathematics passed for magic; and because also of the superstitious operations they were employed in, as the construction of talismans, &c; for, according to the childish philosophy of those days, which ascribed virtues to numbers, what might not be expected from numbers so seemingly wonderful!

The magic square was held in great veneration among the Egyptians, and the Pythagoreans their disciples, who, to add more efficacy and virtue to this square, dedicated it to the then known 7 planets divers ways, and engraved it on a plate of the metal that was esteemed in sympathy with the planet. The square thus dedicated, was inclosed by a regular polygon, inscribed in a circle, which was divided into as many equal parts as there were units in the side of the square; with the names of the angles of the planet, and the signs of the zodiac written upon the void spaces between the polygon and the circumference of the circumscribed circle. Such a talisman or metal they vainly imagined would, upon occasion, befriend the person who carried it about him.

To Saturn they attributed the square of 9 places or cells, the side being 3, and the sum of the numbers in every row 15: to Jupiter the square of 16 places, the side being 4, and the amount of each row 34: to Mars the square of 25 places, the side being 5, and the amount of each row 65: to the sun the square with 36 places, the side being 6, and the sum of each row 111: to Venus the square of 49 places, the side being 7, and the amount of each row 175: to Mercury the square with 64 places, the side being 8, and the sum of each row 260: and to the moon the square of 81 places, the side being 9, and the amount of each row 369. Finally, they attributed to imperfect matter, the square with 4 divisions, having 2 for its side; and to God the square of only one cell, the side of which is also an unit, which multiplied by itself, undergoes no change.

However, what was at first the vain practice of conjurers and makers of talismans, has since become the subject of a serious research among mathematicians. Not that they imagine it will lead them to any thing of solid use or advantage; but rather as it is a kind of play, in which the difficulty makes the merit, and it may chance to produce some new views or properties of numbers, which mathematicians might probably turn to some account.

It would seem that Eman. Moschopulus, a Greek author of no high antiquity, was the first now known of, who has spoken of magic squares: he has left some rules for their construction; though, by the age in which he lived, there is reason to imagine he did not look upon them merely as a mathematician.

In the treatise of Cornelius Agrippa, so much accused of magic, are found the squares of 7 numbers, viz, from 3 to 9 inclusive, disposed magically; and it is not to be supposed that those 7 numbers were preferred to all others without some good reason: indeed it is because their squares, according to the system of Agrippa and his followers, are planetary. The square of 3, for instance, belongs to Saturn; that of 4 to Jupiter; that of 5 to Mars; that of 6 to the sun; that of 7 to Venus; that of 8 to Mercury; and that of 9 to the moon.

M. Bachet applied himself to the study of magic squares, on the hint he had taken from the planetary squares of Agrippa, as being unacquainted with Moschopulus's work, which is only in manuscript in the French king's library; and, without the assistance of any author, he found out a new method for the squares of uneven numbers; for instance, 25, or 49, &c; but he could not succeed with those that have even roots.

M. Frenicle next engaged in this subject. It was the opinion of some, that though the first 16 numbers might be disposed 20922789888000 different ways in a natural square, yet they could not be disposed more than 16 ways in a magic square; but M. Frenicle showed, that they might be thus disposed in 878 different ways. To this business he thought fit to add a difficulty that had not yet been considered; which was, to take away the marginal numbers quite around, or any other circumference at pleasure, or even several of such circumferences, and yet that the remainder should still be magical. Again he inverted that condition, and required that any circumference taken at pleasure, or even several circumferences, should be inseparable from the square; that is, that it should cease to be magical when they were removed, and yet continue magical after the removal of any of the rest. M. Frenicle however gives no general demonstration of his methods, and it often seems that he has no other guide but chance. It is true, his book was not published by himself, nor did it appear till after his death, viz, in 1693.

In 1703, M. Poignard, canon of Brussels, published a treatise on sublime magic squares. Before his time there had been no magic squares made, but for series of natural numbers that formed a square; but M. Poignard made two very considerable improvements. 1st, Instead of taking all the numbers that fill a square, for instance the 36 successive numbers, which would fill all the cells of a natural square whose side is 6, he only takes as many successive numbers as there are units in the side of the square, which in this case are 6; and these six numbers alone he disposes in such manner, in the 36 cells, that none of them occur twice in the same rank, whether it be horizontal, vertical, or diagonal; whence it follows, that all the ranks, taken all the ways possible, must always make the same sum; and this method M. Poignard calls repeated progressions. 2d, Instead of being confined to take these numbers according to the series and succession of the natural numbers, that is in arithmetical progression, he takes them likewise in a geometrical progression; and even in an harmonical one, the numbers of all the ranks always following the same kind of progression: he makes squares of each of these three progressions repeated.

M. Poignard's book gave occasion to M. Lahire to turn his thoughts to the same subject, which he did with such success, that he greatly extended the theory of magic squares, as well for even numbers as those that are uneven; as may be seen at large in the Memoirs of the Royal Academy of Sciences, for the years 1705, and in 1710 by M. Sauveur. See also Saunderson's Algebra, vol. 1, pa. 354, &c; as also my Mathematical Recreations, translated from Ozanam and Montucla, giving the following easy method of filling up a magic square.

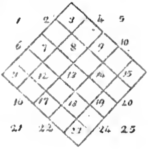
To form a Magic Square of an Odd Number of Terms in the Arithmetic Progression 1, 2, 3, 4, &c. Place the least term 1 in the cell immediately under the middle, or central one, and the rest of the terms, in their natural order, in a descending diagonal direction, till they run off either at the bottom, or on the side: when the number runs off at the bottom, carry it to the uppermost cell that is not occupied, of the same column that it would have fallen in below, and then proceed descending diagonalwise again as far as you can, or till the numbers either run off at bottom or side, or are interrupted by coming at a cell already filled: now when any number runs off at the right-hand side, then bring it to the farthest cell on the left hand of the same row or line it would have fallen in towards the right hand: and when the progress diagonalwise is interrupted by meeting with a cell already occupied by some other number, then descend diagonally to the left from this cell till an empty one is met with, where enter it; and thence proceed as before.

Thus, to make a magic square of the 49 numbers 1, 2, 3, 4, &c. First place the 1 next below the centre cell, and thence descend to the right till the 4 runs off at the bottom, which therefore carry to the top corner on the same column as it would have fallen in; but as it runs off at the side, bring it to the beginning of the second line, and thence descend to the right till you arrive at the cell occupied by 1; carry the 8 therefore to the next diagonal cell to the left, and so proceed till 10 run off at the bottom, which carry there-

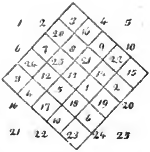
22	47	16	41	10	35	4
5	23	48	17	42	11	29
30	6	24	49	18	36	12
13	31	7	25	43	19	37
38	14	32	1	26	44	20
21	39	8	33	2	27	45
46	15	40	9	34	3	28

fore to the top of its column, and so proceed till 13 runs off at the side, which therefore bring to the beginning of the same line, and thence proceed till 15 arrives at the cell occupied by 8; from this therefore descend diagonally to the left; but as 16 runs off at the bottom, carry it to the top of its proper column, and thence descend till 21 run off at the side, which is therefore brought to the beginning of its proper line; but as 22 arrives at the cell occupied by 15, descend diagonally to the left, which brings it into the 1st column, but off at the bottom, and therefore it is carried to the top of that column; thence descending till 29 runs off both at the bottom and side, which therefore carry to the highest unoccupied cell in the last column; and here, as 30 runs off at the side, bring it to the beginning of its proper column, and thence descend till 35 runs off at the bottom, which therefore carry to the beginning or top of its own column; and here, as 36 meets with the cell occupied by 29, it is brought from thence diagonally to the left; thence descending, 38 runs off at the side, and therefore it is brought to the beginning of its proper line; thence descending, 41 runs off at the bottom, which therefore is carried to the beginning or top of its column; whence descending, 43 arrives at the cell occupied by 36, and therefore it is brought down from thence to the left; thence descending, 46 runs off at the side, which therefore is brought to the beginning of its line; but here, as 47 runs off at the bottom, it is carried to the beginning or top of its column, whence descending with 48 and 49, the square is completed, the sum of every row and column and diagonal making just 175.—There are many other ways of filling up such squares, but none that are easier than that above described; unless perhaps the following mechanical way, communicated by an ingenious friend, Mr. J. B. Wise, of Boyn Hill, near Maidenhead, Berks, which is as follows for an odd number, suppose 5, in the progression 1, 2, 3, 4, 5, &c.

1	2	3	4	5
6	7	8	9	10
11	12	13	14	15
16	17	18	19	20
21	22	23	24	25



First set down the 25 numbers in the form of a square, as in the first diagram here above. Next draw lines cutting off the three figures at each corner, viz, the 1, 2, 6, at the upper left-hand corner; the 4, 5, 10, at the upper right-hand corner; and in like manner 16, 21, 22, and 20, 24, 25 at the bottom corners; which four lines will form a square; then draw inner lines parallel to these, and they will divide the figure into 25 cells, as in the 2d diagram above, in which 13 of the cells will be occupied by as many of the 25 numbers, the other 12 cells being empty, and the filled and empty cells mutually alternating with each other, in every one of the 10 bands.—Lastly, the 12 corner numbers at first cut off, are to be carried into the aforesaid 12 empty cells, in this manner: viz, each of these 12 external numbers is to be carried to the farthest distant empty cell in the band opposite to which it stands; thus, the 2 is carried along its opposite band to the empty cell below the No. 14; in like manner, the 1 is carried to the cell next below 13, the 6 to the cell next below 18, the 4 along its band to the cell next below 12, the 5 to the cell below 13, the 10 to the cell below 18, the 16 to the cell above 8, the 21 to the cell above 13, the 22 to the cell above 14, the 20 to the cell above 8, the 24 to the cell above 12, and the 25 to the cell above 13; thus completing the magic square, as in the 3d diagram, which is a perfect square, the sum of the numbers in every band, and in both the diagonals, making up the same quantity, 65.



For the purpose of perspicuity, in the above process, three diagrams have been employed, in order to exhibit distinctly the several stages of the process; though in fact one diagram only is quite sufficient in practice. And the method is the same for squares of any other odd number of cells.

The same learned friend communicated a great many more of very ingenious constructions of squares, that are much larger and more curious than any that have yet been published, but are too extensive for this place; but it is to be wished that he will himself give them entire to the public in a connected state.

It was observed before, that the sum of the numbers in the rows, columns and diagonals, was 15 in the square of 9 numbers, 34 in a square of 16, 65 in a square of 25, &c; hence then is derived a method of finding the sums of the numbers in any other square, viz, by taking the successive differences till they become equal, and then adding them successively to produce or find out the amount of the following sums. Thus, having ranged the sides and cells in two columns, and a few of the first sums in a third column, take the first differences of these, which will be 1, 4, 10, 19, &c, as in the 4th column; and of these take the differences 0, 3, 6, 9, 12, &c, as in the 5th column; and again of these, the differences 3, 3, 3 &c, as in the 6th or last column. Then, returning back again, add always 3, the constant last or 3d difference, to the last found of the 2d differences, which will complete the remainder of the column of these, viz, 15, 18, 21, 24, &c: then add these 2d differences to the last found of the 1st differences, which will complete the column of these, viz, giving 31, 46, 64, &c: lastly, add always these corresponding 1st differences to the last found number or amount of the sums, and the column of sums will thus be completed.

Side.	Cells.	Sums.	Diffs.		
0	0	0		0	3
1	1	1	1	3	3
2	4	5	4	6	3
3	9	15	10	9	3
4	16	34	19	12	3
5	25	65	31	15	3
6	36	111	46	18	3
7	49	175	64	21	3
8	64	260	85	24	3
9	81	369	109	27	3
10	100	505	136	30	

Again, like as the terms of an arithmetical progression arranged magically, give the same sum in every row &c, so the terms of a geometrical series arranged magically give the same product in every row &c, by multiplying the numbers continually together; so this progression 1, 2, 4, 8, 16, &c, arranged as in the margin, gives, for each continual product, 4096 in every row &c, which is just the cube of the middle term, 16.

8	256	2
4	16	64
128	1	32

Also, the terms of an harmonical progression being ranged magically, as in the margin, have the terms in each row &c in harmonical progression.

1260	840	630
504	420	360
315	280	252

The ingenious Dr. Franklin, it seems, carried this curious speculation further than any of his predecessors in the same way. He constructed both a large Magic Square of Squares, and a Magic Circle of Circles, the description of which may be seen in the collection of his works, with many curious properties; but the square is omitted here, as an imperfection has been detected in the diagonals.

The Magic Circle of Circles, fig. 2, pl. 19, by this author, is composed of a series of numbers, from 12 to 75 inclusive, divided into 8 concentric circular spaces, and ranged in 8 radii of numbers, with the number 12 in the centre; which number, like the centre, is common to all these circular spaces, and to all the radii.

The numbers are so placed, that 1st, the sum of all those in either of the concentric circular spaces above mentioned, together with the central number 12, amount to 360, the same as the number of degrees in a circle.

2. The numbers in each radius also, together with the central number 12, make just 360.

3. The numbers in half of any of the above circular spaces, taken either above or below the double horizontal line, with half the central number 12, make just 180, or half the degrees in a circle.

4. If any four adjoining numbers be taken, as if in a square, in the radial divisions of these circular spaces; the sum of these, with half the central number, make also the same 180.

5. There are also included four sets of other circular spaces, bounded by circles that are excentric with regard to the common centre; each of which sets contain five spaces; and their centres being at A, B, C, D. For distinction, these circles are drawn with different marks, some dotted, others by short unconnected lines, &c; or still better with inks of divers colours, as blue, red, green, yellow.

These sets of excentric circular spaces intersect those of the concentric, and each other; and yet, the numbers contained in each of the excentric spaces, taken all around through any of the 20, which are excentric, make the same sum as those in the concentric, namely 360, when the central number 12 is added. Their halves also, taken above or below the double horizontal line, with half the central number, make up 180. It is observable, that there is not one of the numbers but what belongs at least to two of the circular spaces; some to three, some to four, some to five: and yet they are all so placed, as never to break the required number 360, in any of the 28 circular spaces within the primitive circle. They have also other properties. See Franklin's Exp. and Obs. pa. 350, edit. 4to, 1769; or Ferguson's Tables and Tracts, 1771, pa 318; or my Recreations, vol. 1, pa. 183.

In Dr. Franklin's magic square, above-mentioned, three accidentally erroneous numbers have been detected by Isaac Dalby, Esq. first-professor at the Royal Military College, which he has communicated, as well as the discovery of a radical imperfection in the square, owing to an inequality in the two diagonals: for though the half diagonals have the proper sums, yet the whole diagonals have not. Mr. Dalby has therefore constructed another perfect magic square of magic squares, engraven on pl. 19, fig. 1. the properties of which are as below.

This magic square, made with the series 1, 2, 3, 4, &c, to 256, is composed of 16 magic squares of 16 cells each; the 4 numbers in each column, or diagonal of each of these squares, make 514, and consequently each column or diagonal of the great square is 514 × 4 or 2056.

The principal properties are

1. The sum of the 4 numbers in any 4 contiguous cells forming a square (the square of 2) is 514; thus, 226 + 32 + 255 + 1 = 514; and 1 + 242 + 240 + 31 = 514, &c. Consequently

2. The sum of the 16 numbers in any 16 cells making a square (the square of 4) is 514 × 4 = 2056:— in any square of 36 cells (the square of 6) the sum is 514 × 9: —and 514 × 16 in a square of 64 cells:—514 × 25 in that of 100 cells:—514 × 36 in a square of 144 cells:— and 514 × 49 in any square having 14 for its side. Thus if a square hole just the size of 16 cells be cut in a paper, and the paper laid any where upon the great square, the sum of the 16 numbers appearing through the hole will always be 514 × 4. If the hole takes in 36 cells, the sum is 514 × 9: &c.

3. The sum of the 4 corner numbers of either of these squares will always be 514.

4. The sum of the 16 numbers in any bent row whose halves are parallel to the diagonals is 2056: thus, from 26 to 36, and from 173 to 151, is a bent row; also, from 74 to 22, and from 227 to 191 another bent row, &c.

5. If the square be divided horizontally, or vertically, through the middle, the halves may change places, and the properties of the square will remain as before.

6. If the square be cut into the 16 squares, it is manifest that any four of them will make a magic square of 64 cells; and any nine another magic square of 144 cells; consequently as many different magic squares of 64 cells, and also of 144 cells, may be made with the 16 squares, as there are combinations of 4 in 16, and of 9 in 16.

The construction of the great square evidently depends upon that of a magic square of 16 cells having the sum of the 4 numbers in any square composed of 4 cells always the same. To construct such a square with the series 1, 2, 3, 4, &c. to 16. *First*, $\frac{(16+1)\times 8}{4} = 34$ the sum in each column or diagonal, or in the 4 cells. Now arrange the 16 numbers as in fig. 1., then by the nature of the progression, each diagonal will contain 34: and the excess above 34 in the 4th perpendicular column on the right is equal to the defect in the 1st column on the left; and the excess and defect in the lower and upper horizontal columns are also

Fig. 1.

1	5	9	13
2	6	10	14
3	7	11	15
4	8	12	16

the same; hence (the corner numbers remaining) if 2 and 15, 3 and 14, 5 and 12, 9 and 8 respectively change places, we have the magic square fig. 2. In this square, however, only the middle square of 4 cells, and the 4 corner ones contain 34 each: but in magic squares we readily obtain varieties by shifting the columns: thus in fig. 2, the 2d vertical column from the left may be made the last on the right, or the 3d from the left made the 1st, and the two upper, or the two lower horizontal columns take place of one another; either of these arrangements will answer: thus, let the 3d vertical column be brought on the left, and change the two upper horizontal columns one for the other, and we get the magic square fig. 3, having 34 in any square of 4 cells.

Fig. 2.

4	9	5	16

Fig. 3.

10	15	6	3
8	1	12	13
11	14	7	2
5	4	9	16

It will now be perceived that the numbers in fig. 3, consist of pairs situated alternately, the sums being 18 and 16 respectively; thus 10 + 8, 15 + 1, 6 + 12, &c, are pairs. Hence, to make the great square with the series 1, 2, 3, 4, &c. to 256, let the numbers be arranged thus

256 255 254 253 252 251 &c.
2 1 4 3 6 5

the pairs making 258, 256, 258, &c, and call the upper or greater numbers the complements of the lower or lesser numbers: then arrange the first 32 numbers of the lower series (consisting of the numbers from 1 to 128) as in the margin: next, place the 8 upper numbers with their complements in a square of 16 cells in the same order, from the least to the greatest, as they stand in fig. 3, and we shall have the first or corner square of the great square on the left at top.

1	16	17	32
2	15	18	31
3	14	19	30
4	13	20	29
5	12	21	28
6	11	22	27
7	10	23	26
8	9	24	25

In fig. 3.	1	2	3	4	5	6	7	8	9	10	11	12	13
Correspond. numb.	1	2	15	16	17	18	31	32	225	226	239	240	241
In fig. 3.	14	15	16										
Correspond numb.	242	255	256										

The next 8 numbers, or 3, 4, 13, 14, 19, 20, 29, 30, with their complements, make the 2d square downwards, and so on for the four first squares on the left. And for the next 4 squares, the numbers from 32 to 64 are arranged as above: and two more arrangements, viz, from 64 to 96, and from 96 to 128, in the same manner, will complete the 16 squares.

It is already remarked that the pairs fall alternately in fig. 3; and the same order necessarily results in the great square; the pairs making 258 and 256 throughout: and 258 + 256 = 514; therefore when two numbers with their complements occupy a square of 4 cells, it is obvious their sum is 514; but the sum will also be equal to 258 + 256, when the 4 numbers belong to 4 pair, the excess on one side being equal to the defect on the other; thus, taking the numbers in the 2d and 3d horizontal columns by fours, 32 + 239 = 271, 1 + 242 = 243, now 271 − 256 = 15, and 258 − 243 = 15, therefore 271 + 243 = 258 + 256; and the like of any other 4 adjacent numbers in the two ranks.

But Dr. Franklin, instead of taking 256 and 258 alternately, begins with two pair of 258 in succession: thus, 200 + 58 = 258, the first pair at top; then 198 + 60 = 258, the next under; and these are followed by four pair of 256 each; thus, 201 + 55 = 256, the first pair; then 203 + 53 = 256 the next under, &c; and the two pair at the bottom of the column are 258 each, or 196 + 62, and 194 + 64. His 2d vertical column begins at top with two pair of 256 each, and these are followed by four pair of 258. In this manner he has a regular alternation of 2 pair and 4 pair, throughout his square; but this construction will not answer diagonally, and therefore his square is radically wrong, and cannot be mended but by a new one.

The doctor's smaller square too, of 64 cells (in plate 5 in his Works), is constructed in a manner similar to his large one, namely, by pairs of numbers, whose sums are 66 and 64; but, instead of these sums or pairs being alternate, we find 66 first, then two of 64 each; next 66 (taking the first vertical column on the left, and proceeding downwards): this order runs through the whole square, and in consequence it fails diagonally, one diagonal being 292, the other 228.

Last year Mr. Youle, schoolmaster at Sheffield, published an Arithmetic, to which is added a tract on magic squares: in this we are informed, that the Rev. Mr. Watson of Whitby, in a small treatise lately published, has noticed the deficiencies in Doctor Franklin's square, and has given a magic square of 256 cells, with the following additional property, viz—"the 4 corner numbers of every interior square whose root is an even number, whether concentric or not to the great square, always make 514."

Watson has also analysed the doctor's magic circle of circles, which is made with the numbers of a magic square of 64 cells (the numbers from 12 to 75).

The square in Youle's book is constructed with pairs of 256 and 258, as in Dr. F.'s and mine: but Youle's theory and mine are totally different.

MAGICAL *Picture,* in Electricity, was first contrived by Mr. Kinnersley, and is thus constructed: Having a large mezzotinto with a frame and glass, as of the king for instance, take out the print, and cut a pannel out of it, near two inches distant from the frame all around; then with thin paste or gum-water, fix the border that is cut off on the inside of the glass, pressing it smooth and close; then fill up the vacancy by gilding the glass well with leaf-gold or brass. Gild likewise the inner edge of the back of the frame all around, except the top part, and form a communication between that gilding and the gilding behind the glass; then put in the board, and that side is finished. Next turn up the glass, and gild the foreside exactly over the back gilding, and when it is dry, cover it by pasting on the pannel of the picture that has been cut out, observing to bring the corresponding parts of the border and picture together, by which means the picture will appear entire, as at first, only part behind the glass, and part before.

Hold the picture horizontally by the top, and place a small moveable gilt crown on the king's head. If now the picture be moderately electrified, and another person take hold of the frame with one hand, so that his fingers touch its inside gilding, and with the other hand endeavour to take off the crown, he will receive a violent blow, and fail in the attempt. If the picture were highly charged, the consequence might be as fatal as that of high treason. The operator, who holds the picture by the upper end, where the inside of the frame is not gilt, to prevent its falling, feels nothing of the shock, and may touch the face of the picture without danger. And if a ring of persons take the shock among them, the experiment is called the conspirators. See Franklin's Exper. and Observ. pa. 30.

MAGINI (John-Anthony), or Maginus, professor of mathematics in the university of Bologna, was born at Padua in the year 1536. Magini was remarkable for his great assiduity in acquiring and improving the knowledge of the mathematical sciences, with several new inventions for these purposes, and for the extraordinary favour he obtained from most princes of his time. This doubtless arose partly from the celebrity he had in matters of astrology, to which he was greatly addicted, making horoscopes, and foretelling events, both relating to persons and things. He was invited by the Emperor Rodolphus to come to Vienna, where he promised him a professor's chair, about the year 1597; but not being able to prevail on him to settle there, he nevertheless gave him a handsome pension.

It is said, he was so much addicted to astrological predictions, that he not only foretold many good and evil events relative to others with success; but even foretold his own death, which came to pass the same year: all which he represented as under the influence of the stars. Tomasini says, that Magini, being advanced to his 61st year, was struck with an apoplexy, which ended his days; and that a long while before, he had told him and others, that he was afraid of that year. And Roffeni, his pupil, says, that Magini died under an aspect of the planets, which, according to his own prediction, would prove fatal to him; and he mentions Riccioli as affirming that he said, the figure of his nativity, and his climacteric year, doomed him to die about that time; which happened in 1618, in the 62d year of his age.

His writings however do honour to his memory, as they were very considerable, and on learned subjects. The principal were the following: 1. His Ephemeris, in 3 volumes, from the year 1580 to 1630.—2. Tables of Secondary Motions.—3. Astronomical, Gnomonical, and Geographical Problems.—4. Theory of the Planets, according to Copernicus.—5. A Confutation of Scaliger's Dissertation concerning the Precession of the Equinox.—6. A Primum Mobile, in 12 books.—7. A Treatise of Plane and Spherical Trigonometry.—8. A Commentary on Ptolemy's Geography.—9. A Chorographical Description of the Regions and Cities of Italy, illustrated with 60 maps; with some papers on astrological subjects.

MAGNET, Magnes, the *Loadstone;* a kind of ferruginous stone, resembling iron ore in weight and colour, though rather harder and heavier; and is endued with divers extraordinary properties, attractive, directive, inclinatory, &c. See Magnetism.

The magnet is also called lapis Heraclæus, from Heraclea, a city of Magnesia, a port of the ancient Lydia, where it was said to have been first found, and from which it is usually supposed that it took its name. Though some derive the word from a shepherd named Magnes, who first discovered it on mount Ida with the iron of his crook. It is also called lapis nauticus, from its use in navigation: also siderites, from its virtue in attracting iron, which the Greeks call σιδηρος.

The magnet is usually found in iron-mines, and sometimes in very large pieces, half magnet, half iron. Its colour is different, as found in different countries. Norman observes, that the best are those brought from China and Bengal, which are of a rusty or sanguine colour; those of Arabia are reddish; those of Macedonia, blackish; and those of Hungary, Germany, England, &c, the colour of unwrought iron. Neither its figure nor bulk are constant or determined; being found of all shapes and sizes.

The ancients reckoned five kinds of magnets, different in colour and virtue: the Ethiopic, Magnesian, Bœotic, Alexandrian, and Natolian. They also fancied it to be male and female: but the chief use they made of it was in medicine; especially for the cure of burns and defluxions of the eyes.—The moderns, more happy, take it to conduct them in their voyages.

The most distinguishing properties of the magnet are: That it attracts iron, and that it points towards the poles of the world; and in other circumstances also dips or inclines to a point beneath the horizon, directly under the pole; it also communicates these properties, by contact to iron. By means of which, are obtained the mariner's needles, both horizontal and inclinatory or dipping needles.

The Attractive Power of the Magnet, was known to the ancients, and is mentioned even by Plato and Euripides, who call it the Herculean stone, because it commands iron, which subdues every thing else: but the knowledge of its directive power, by which it disposes its poles along the meridian of every place, or nearly so, and causes needles, pieces of iron, &c, touched with it, to point nearly north and south also, is of a much later date though the discoverer himself, and the exact time of the discovery, be not now known. The first mention of it is about 1260, when it has been said that Marco Polo, a Venetian, introduced the mariner's compass; though not as an invention of his own, but as derived from the Chinese, who it seems had the use of it long before; though some imagine that the Chinese rather borrowed it from the Europeans.

But Flavio de Gira, a Neapolitan, who lived in the 13th century, is the person usually supposed to have the best title to the discovery; and yet Sir G. Wheeler mentions that he had seen a book of astronomy much older, which supposed the use of the needle; though not as applied to the purposes of navigation, but of astronomy. And in Guiot de Provins, an old French poet, who wrote about the year 1180, there is an express mention made of the loadstone and the compass; and their use in navigation obliquely hinted at.

The Variation of the Magnet, or needle, or its deviation from the pole, was first discovered by Sebastian Cabot, a Venetian, in 1500; and the variation of that variation, or change in its direction, by Mr. Henry Gellibrand, professor of astronomy in Gresham-college, about the year 1625. Lastly, the dip or inclination of the needle, when at liberty to play vertically, to a point beneath the horizon, was first discovered by another of our countrymen, Mr. Robert Norman, about the year 1576.

The Phenomena of the Magnet, are as follow: 1, In every magnet there are two poles, of which the one points northwards, the other southwards, when it is freely suspended; and if the magnet be divided into ever so many pieces, the two poles will be found in each piece. The poles of a magnet may be found by holding a very fine short needle over it; for where the poles are, the needle will stand upright, but no where else.—2, These poles, in different parts of the globe, are differently inclined towards a point under the horizon.—3, And, though contrary to each other, do help mutually towards the magnet's attraction and suspension of iron.—4, If two magnets be spherical, one will turn or conform itself to the other, so as either of them would do to the earth; and after they have so conformed or turned themselves, they endeavour to approach or join each other; but if placed in a contrary position, they avoid each other.—5, If a magnet be cut through the axis, the segments or parts of the stone, which before were joined, will now avoid and fly each other.—6, If the magnet be cut perpendicular to its axis, the two points, which before were conjoined, will become contrary poles; one in each segment.—7, Iron receives virtue from the magnet by application to it, or barely from an approach near it, though it do not touch it; and the iron receives this virtue variously, according to the parts of the stone it is made to touch, or even approach to.—8, If an oblong piece of iron be in any manner applied to the stone, it receives virtue from it only lengthways.—9, The magnet loses none of its own virtue by communicating any to the iron; and this virtue it can communicate to the iron very speedily: though the longer the iron joins or touches the stone, the longer will it maintain its communicated virtue; and a better magnet will communicate more of it, and sooner, than one not so good.—10, Steel receives virtue from the magnet better than iron.—11, A needle touched by a magnet will turn its ends the same way towards the poles of the world, as the magnet itself does.—12, Neither loadstone nor needles touched by it conform their poles exactly to those of the world, but have usually some variation from them: and this variation is different in different places, and at divers times in the same places.—13, A loadstone will take up much more iron when armed, or capped, than it can alone. (A loadstone is said to be armed, when its poles are surrounded with plates of steel: and to determine the quantity of steel to be applied, try the magnet with several steel bars; and the greatest weight it takes up, with a bar on, is to be the weight of its armour.) And though an iron ring or key be suspended by the loadstone, yet this does not hinder the ring or key from turning round any way, either to the right or left.—14, The force of a loadstone may be variously increased or lessened, by variously applying to it, either iron, or another loadstone.—15, A strong magnet at the least distance from a smaller or weaker one, cannot draw to it a piece of iron adhering actually to such smaller or weaker stone; but if it touch it, it can draw it from the other: but a weaker magnet, or even a small piece of iron, can draw away or separate a piece of iron contiguous to a larger or stronger magnet.—16, In these northern parts of the world, the south pole of a magnet will raise up more iron than its north pole.—17, A plate of iron only, but no other body interposed, can impede the operation of the loadstone, either as to its attractive or directive quality.—18, The power or virtue of a loadstone may be impaired by lying long in a wrong position, as also by rust, wet, &c; and may be quite destroyed by fire, lightning, &c.—19, A piece of iron wire well touched, on being bent round in a ring, or coiled round on a stick, &c, will always have its directive virtue diminished, and often quite destroyed. And yet if the whole length of the wire were not entirely bent, so that the ends of it, though but for the length of one-tenth of an inch, were left straight, the virtue will not be destroyed in those parts; though it will in all the rest.—20, The sphere of activity of magnets is greater and less at different times. Also, the variation of the needle from the meridian, is various at different times of the day.—21, By twisting a piece of wire touched with a magnet, its virtue is greatly diminished; and sometimes so disordered and confused, that in some parts it will attract, and in others repel; and even, in some places, one side of the wire seems to be attracted, and the other side repelled, by one and the same pole of the stone.—22, A piece of wire that has been touched, on being split, or cleft in two, the poles are sometimes changed, as in a cleft magnet; the north pole becoming the south, and the south the north: and yet sometimes one half of the wire will retain its former poles, and the other half will have them changed.—23, A wire being touched from end to end with one pole of a magnet, the end at which you begin will always turn contrary to the pole that touched it: and if it be again touched the same way with the other pole of the magnet, it will then be turned the contrary way.—24, If a piece of wire be touched in the middle with only one pole of the magnet, without moving it backwards or forwards; in that place will be the pole of the wire, and the two ends will be the other pole.—25, If a magnet be heated red-hot, and again cooled either with its south pole towards the north in a horizontal position, or with its south pole downwards in a perpendicular position, its poles will be changed.—26, Mr. Boyle (to whom we are indebted for the following magnetical phenomena) found he could presently change the poles of a small fragment of a loadstone, by applying them to the opposite vigorous poles of a large one.—27, Hard iron tools well tempered, when heated by a brisk attrition, as filing, turning, &c, will attract thin filings or chips of iron, steel, &c; and hence we observe that files, punches, augres, &c, have a small degree of magnetic virtue.—28, The iron bars of windows, &c, which have stood a long time in an erect position, grow permanently magnetical; the lower ends of such bars being the north pole, and the upper end the south pole.—29, A bar of iron that has not stood long in an erect posture, if it be only held perpendicularly, will become magnetical, and its lower end the north pole, as appears from its attracting the south pole of a needle: but then this virtue is transient, and by inverting the bar, the poles change their places. In order therefore to render the quality permanent in an iron bar, it must continue a long time in a proper position. But fire will produce the effect in a short time: for as it will immediately deprive a loadstone of its attractive virtue; so it soon gives a verticity to a bar of iron, if, being heated red hot, it be cooled in an erect posture, or directly north and south. Even tongs and fire-forks, by being often heated, and set to cool again in a posture nearly erect, have gained this magnetic property. Sometimes iron bars, by long standing in a perpendicular position, have acquired the magnetic virtue in a surprising degree. A bar about 10 feet long, and three inches thick, supporting the summer beam of a room, was able to turn the needle at 8 or 10 feet distance, and exceeded a loadstone of 3½ pounds weight: from the middle point upwards it was a north pole, and downwards a south pole. And Mr. Martin mentions a bar, which had been the beam of a large steelyard that had several poles in it.—30, Mr. Boyle found, that by heating a piece of English oker red-hot, and placing it to cool in a proper posture, it manifestly acquired a magnetic virtue. And an excellent magnet, belonging to the same ingenious gentleman, having lain near a year in an inconvenient posture, had its virtue greatly impaired, as if it had been by fire.—31, A needle well touched, it is known, will point north and south: if it have one contrary touch of the same stone, it will be deprived of its faculty; and by another such touch, it will have its poles interchanged.—32, If an iron bar have gained a verticity by being heated red-hot and cooled again, north and south, and then hammered at the two ends; its virtue will be destroyed by two or three smart blows on the middle.—33, By drawing the back of a knife, or a long piece of steel-wire, &c, leisurely over the pole of a loadstone, carrying the motion from the middle of the stone to the pole; the knife or wire will attract one end of a needle; but if the knife or wire be passed from the said pole to the middle of the stone, it will repel the same end of the needle.—34, Either a magnet or a piece of iron being laid on a piece of cork, so as to float freely on water; it will be found, that, whichever of the two is held in the hand, the other will be drawn to it: so that iron attracts the magnet as much as it is attracted by it; action and re-action being always equal. In this experiment, if the magnet be set afloat, it will direct its two poles to the poles of the world nearly.—35, A knife &c touched with a magnet, acquires a greater or less degree of virtue, according to the part it is touched on. It receives the strongest virtue, when it is drawn leisurely from the handle towards the point over one of the poles. And if the same knife thus touched, and thus possessed of a strong attractive power, be retouched in a contrary direction, viz, by drawing it from the point towards the handle over the same pole, it immediately loses all its virtue.—36, A magnet acts with equal force in vacuo as in the open air.—37, The smallest magnets have usually the greatest power in proportion to their bulk. A large magnet will seldom take up above 3 or 4 times its own weight, while a small one will often take up more than ten times its weight. A magnet worn by Sir Isaac Newton in a ring, and which weighed only 3 grains, would take up 746 grains, or almost 250 times its own weight. A magnetic bar made by Mr. Canton, weighing 10 oz. 12 dwts, took up more than 79 ounces; and a flat semicircular steel magnet, weighing 1 oz. 13 dwts, took up an iron wedge of 90 ounces.

Armed MAGNET, denotes one that is capped, cased, or set in iron or steel, to make it take up a greater weight, and also more readily to distinguish its poles. For the methods of doing this, see Mr. Michell's book on this subject.

Artificial MAGNET, is a bar of iron or steel, impregnated with the magnetic virtue, so as to possess all the properties of the natural loadstone, and be used instead of it. How to make magnets of this kind, by means of a natural magnet, and even without the assistance of any magnet, was suggested many years since by Mr. Savary, and particularly described in the Philos. Trans. No. 414. See also my Abridgment, vol. 7, pa. 400. But as his method was tedious and operose, though capable of communicating a very considerable virtue, it was little practised. Dr. Gowin Knight first brought this kind of magnets to their present state of perfection, so as to be even of much greater efficacy than the natural ones. But as he foolishly refused to discover his methods on a terms whatever, these curious and valuable secrets a great measure died with him. The result of his meth however was first published in the Philos. Trans. for 17 art. 8, and for 1745, art. 3. See also the vol. for 17 art. 2. And in the 69th vol. Mr. Benjamin Wilson given a process, which at least discovers one of the lead principles of Dr. Knight's art. The method, according Mr. Wilson, was as follows. Having provided a gr quantity of clean iron filings, he put them into a large t that was more than one-third filled with clean water; then, with great labour, shook the tub to and fro for ma hours together, that the friction between the grains iron, by this treatment, might break or rub off such sm parts as would remain suspended in the water for so time. The water being thus rendered very muddy, poured it into a clean iron vessel, leaving the filings behi and when the water had stood long enough to beco clear, he poured it out carefully, without disturbing su of the sediment as still remained, which now appea reduced almost to impalpable powder. This powder w afterwards removed into another vessel, to dry it: a having, by several repetitions of the process, procure sufficient quantity of this very fine powder; the next thi was to make a paste of it, and that with some vehicle co taining a good quantity of the phlogistic principle; this purpose, he had recourse to linseed oil, in preferen to all other fluids: and with these two ingredients only, made a stiff paste, and took great care to knead it w before he moulded it into convenient shapes. Sometim while the paste continued in its soft state, he would p the impression of a seal; one of which is in the Britt Museum. This paste so moulded was then set up wood, or a tile, to dry or bake it before a moderate fi being placed at about one foot distance. He found th a moderate fire was most proper, because a greater degr of heat would make the composition crack in ma places. The time requisite for the baking or drying of th paste, was usually about 5 or 6 hours, before it attained sufficient degree of hardness. When that was done, an the several baked pieces were become cold, he gave the their magnetic virtue in any direction he pleased, b placing them between the extreme ends of his large m gazine of artificial magnets, for a few seconds. The virtu they acquired by this method was such, that, when an of those pieces were held between two of his best ten-gu nea bars, with its poles purposely inverted, it immediatel of itself turned about to recover its natural directio which the force of those very powerful bars was not suff cient to counteract. Philos. Trans. vol. 65, for 1779.

Methods for artificial magnets were also discovered an published by the Rev. Mr. John Michell, in a Treatise o Artificial Magnets, printed in 1750, and by Mr. Joh Canton, in the Philos. Trans. for 1751. The process fo the same purpose was also found out by other persons particularly by Du Hamel, Hist. Acad. Roy. 1745 an 1750, and by Marul Uitgelecze Natuurkund. Verhand tom. 2, p. 261.

Mr. Canton's method is as follows: Procure a dozen of bars; 6 of soft steel, and 6 of hard; the former to be each 3 inches long, a quarter of an inch broad, and 1-20th of an inch thick; with two pieces of iron, each half the length of one of the bars, but of the same breadth and thickness; and the 6 hard bars to be each 5½ inches long, half an inch broad, and 3-20ths of an inch thick, with two pieces of iron of half the length, but the whole breadth and thickness of one of the hard bars; and let all the bars be marked with a line quite around them at one end. Then take an iron poker and tongs (fig. 1, plate 20), or two bars of iron, the larger they are, and the longer they have been used, the better; and fixing the poker upright between the knees, hold to it, near the top, one of the soft bars, having its marked end downwards by a piece of sewing-silk, which must be pulled tight by the left hand, that the bar may not slide: then grasping the tongs with the right hand, a little below the middle, and holding them nearly in a vertical position, let the bar be stroked by the lower end, from the bottom to the top, about ten times on each side, which will give it a magnetic power sufficient to lift a small key at the marked end: which end, if the bar were suspended on a point, would turn towards the north, and is therefore called the north pole; and the unmarked end is, for the same reason, called the south pole. Four of the soft bars being impregnated in this manner, lay the two (fig. 2) parallel to each other, at a quarter of an inch distance, between the two pieces of iron belonging to them, a north and a south pole against each piece of iron: then take two of the four bars already made magnetical, and place them together, so as to make a double bar in thickness, the north pole of one even with the south pole of the other; and the remaining two being put to these, one on each side, so as to have two north and two south poles together, separate the north from the south poles at one end by a large pin, and place them perpendicularly with that end downward on the middle of one of the parallel bars, the two north poles towards its south end, and the two south poles towards its north end: slide them three or four times backward and forward the whole length of the bar; then removing them from the middle of this bar, place them on the middle of the other bar as before directed, and go over that in the same manner; then turn both the bars the other side upwards, and repeat the former operation: which being done, take the two from between the pieces of iron; and, placing the two outermost of the touching bars in their stead, let the other two be the outermost of the four to touch these with; and this process being repeated till each pair of bars have been touched three or four times over, which will give them a considerable magnetic power. Put the half-dozen together after the manner of the four (fig. 3), and touch them with two pair of the hard bars placed between their irons, at the distance of about half an inch from each other; then lay the soft bars aside, and with the four hard ones let the other two be impregnated (fig. 4), holding the touching bars apart at the lower end near ⅟th of an inch; to which distance let them be separated after they are set on the parallel bar, and brought together again before they are taken off: this being observed, proceed according to the method described above, till each pair have been touched two or three times over. But as this vertical way of touching a bar, will not give it quite so much of the magnetic virtue as it will receive, let each pair be now touched once or twice over in their parallel position between the irons (fig. 5), with two of the bars held horizontally, or nearly so, by drawing at the same time the north end of one from the middle over the south end, and the south of the other from the middle over the north end of a parallel bar; then bringing them to the middle again, without touching the parallel bar, give three or four of these horizontal strokes to each side. The horizontal touch, after the vertical, will make the bars as strong as they possibly can be made, as appears by their not receiving any additional strength, when the vertical touch is given by a great number of bars, and the horizontal by those of a superior magnetic power.

This whole process may be gone through in about half an hour; and each of the large bars, if well hardened, may be made to lift 28 troy ounces, and sometimes more. And when these bars are thus impregnated, they will give to a hard bar of the same size its full virtue in less than two minutes; and therefore will answer all the purposes of magnetism in navigation and experimental philosophy, much better than the loadstone, which has not a power sufficient to impregnate hard bars. The half dozen being put into a case (fig. 6), in such a manner as that no two poles of the same name may be together, and their irons with them as one bar, they will retain the virtues they have received; but if their power should, by making experiments, be ever so far impaired, it may be restored without any foreign assistance in a few minutes. And if perchance a much larger set of bars should be required, these will communicate to them a sufficient power to proceed with; and they may, in a short time, by the same method, be brought to their full strength.

MAGNETISM, the quality or constitution of a body, by which it is rendered magnetical, or a magnet, sensibly attracting iron, and giving it a meridional direction.—This is a transient power, capable of being produced, destroyed, or restored.

The Laws of MAGNETISM.—These laws are laid down by Mr. Whiston in the following propositions.—1. The loadstone has both an attractive and a directive power united together, while iron touched by it has only the former; i. e. the magnet not only attracts needles, or steel filings, but also directs them to certain different angles, with respect to its own surface and axis; whereas iron, touched with it, does little or nothing more than attract them; still suffering them to lie along or stand perpendicular to its surface and edges in all places, without any such special direction.

2. Neither the strongest nor the largest magnets give a better directive touch to needles, than those of a less size or virtue: to which may be added, that whereas there are two qualities in all magnets, an attractive and a directive one, neither of them depend on, or are any proof of, the strength of the other.

3. The attractive power of magnets, and of iron, will greatly increase or diminish the weight of needles on the balance; nay, it will overcome that weight, and even sustain some other additional also: while the directive power has a much smaller effect. Gassendus indeed, as well as Mersennus and Gilbert, assert that it has none at all: but this is a mistake; for Whiston found, from repeated trials on large needles, that after the touch they weighed less than before. One of 4584½ grains, lost 2¼ grains by the touch; and another of 65726 grains weight, no less than 14 grains.

4. It is probable that iron consists almost wholly of the attractive particles; and the magnet, of the attractive and directive together; mixed, probably, with other heterogeneous matter; as having never been purged by the fire, which iron has; and hence may arise the reason why iron, after it has been touched, will lift up a much greater weight than the loadstone that touched it.

5. The quantity and direction of magnetic powers,

communicated to needles, are not properly, after such communication, owing to the magnet which gave the touch; but to the goodness of the steel that receives it, and to the strength and position of the terrestrial loadstone, whose influence alone those needles are afterwards subject to, and directed by: so that all such needles, if good, move with the same strength, and point to the same angle, whatever loadstone they may have been excited by, provided it be but a good one Nor does it seem that the touch does much more in magnetical cases, than attrition does in electrical ones; i. e. serving to rub off some obstructing particles, that adhere to the surface of the steel, and opening the pores of the body touched, thus making way for the entrance and exit of such effluvia as occasion or assist the powers we are speaking of. Hence Mr. Whiston takes occasion to observe, that the directive power of the loadstone seems to be mechanical, and to be derived from magnetic effluvia, circulating continually about it.

6. The absolute attractive power of different armed loadstones, is, cæteris paribus, not according to either the diameters or solidities of the loadstones, but according to the quantity of their surfaces, or in the duplicate proportion of their diameters.

7. The power of good unarmed magnets, sensibly equal in strength, similar in figure and position, but unequal in magnitude, is sometimes a little greater, sometimes a little less, than in the proportion of their similar diameters.

8. The loadstone attracts needles that have been touched, and others that have not been touched, with equal force at unequal distances, viz. when the distance of the former is to the distance of the latter, as 5 to 2.

9. Both poles of a magnet equally attract needles, till they are touched; then it is, and then only, that one pole begins to attract one end, and repel the other: though the repelling pole will still attract upon contact, and even at very small distances.

10. The attractive power of loadstones, in their similar position to, but different distances from, magnetic needles, is in the sesquiduplicate proportion of the distances of their surfaces from their needles reciprocally; or as the mean proportionals between the squares and the cubes of those distances reciprocally; or inversely as the square roots of the 5th powers of those distances. Thus, the magnetic force of attraction, at twice the distance from the surface of the loadstone, is between a 5th and 6th part of the force at the first distance; at thrice the distance, the force is between the 15th and 16th part; at four times the distance, the power is the 32d part of the first; and at six times the distance, it is the 88th part. Where it is to be noted, that the distances are not counted from the centre, as in the laws of gravity, but from the surface: as experience teaches us, that the magnetic power resides chiefly, if not wholly, in the surfaces of the loadstone and iron; without any particular relation to any centre whatever. The proportion here laid down was determined by Mr. Whiston from a great number of experiments by Mr. Hawksbee, Dr. Brook Taylor, and by Mr. Whiston himself; measuring the force by the chords of those arcs by which the magnet at several distances draws the needle out of its natural direction; to which chords, as he demonstrates, it is always proportional. The numbers in some of their most accurate trials, he gives in the following table, setting down the half chords, or the sines of half those arcs of declination, as the true measures of the force of magnetic attraction.

Distances in inches.	Degrees of inclination.	Sines of ½ arcs.	Sesquiduplicate ratio.
20	2	175	466
14 5/9	4	349	216
13 1/5	6	523	170
12 1/4	8	697	138
11 1/3	10	871	105
10 3/4	12	1045	87
9 1/4	14	1219	70

Other persons however have found some variatio the proportions of the magnetic force with respect t tance: Thus, Newton supposes it to decrease nearly i triplicate ratio of the distance: Mr. Martin observes, the power of his loadstone decreases in the sesquidupl ratio of the distances inversely: but Dr. Helsham and Michell found it to be as the square of the distanc versely: while others, as Dr. Brook Taylor and M. chenbroek, are of opinion, that this power follows no tain ratio at all, and that the variation is different ir ferent stones.

11. An inclinatory, or dipping-needle of 6 inches ra and of a prismatic or cylindric figure, when it oscil along the magnetic meridian, performs there every r vibration in about 6″ or 360‴, and every small oscill in about 5″½, or 330‴: and the same kind of needl feet long, makes every mean oscillation in about 24″, every small one in about 22″.

12. The whole power of magnetism in this countr it affects needles a foot long, is to that of gravity, n as 1 to 300; and as it affects needles 4 feet long, as 600.

13. The quantity of magnetic power accelerating same dipping-needle, as it oscillates in different ver planes, is always as the cosines of the angles mad those planes with the magnetic meridian, taken on horizon.

Thus, in estimating the quantity of force in the rizontal and in the vertical situations of needles at Lon it is found that the latter, in needles of a foot long, i the whole force along the magnetic meridian, as 96 to 1 and in needles 4 feet long, as 9667 to 10000: wher in the former, the whole force in needles of a foot lon as 28 to 100; and in those of 4 feet long, as 256 to 1 Whence it follows, that the power by which horizo needles are governed in these parts of the world, is the quarter of the power by which the dipping-needl moved.

Hence also, as the horizontal needle is moved only a part of the power that moves the dipping-needle; as it only points to a certain place in the horizon, beca that place is the nearest to its original tendency of that its situation will allow it to tend to; whenever dipping-needle stands exactly perpendicular to the rizon, the horizontal needle will not respect one poin the compass more than another, but will wheel about way uncertainly.

14. The time of oscillation and vibration, both in d ping and horizontal needles, that are equally good, is their length directly; and the actual velocities of th points along their arcs are always unequal. And hen magnetical needles are, cæteris paribus, still better, longer they are; and that in the proportion of th lengths.

Of the Causes of MAGNETISM. Though many auth have proposed hypotheses concerning the cause of m netism, as Plutarch, Descartes, Boyle, Newton, Gilbert, Hartsoeker, Halley, Whiston, Knight, Beccaria, &c; nothing however has yet appeared that can be called a satisfactory solution of its phenomena. It is certain indeed, that both natural and artificial electricity will give polarity to needles, and even reverse their poles; but though from this it may appear probable that the electric fluid is also the cause of magnetism, yet in what manner the fluid acts while producing the magnetical phenomena, seems to be quite unknown.

Dr. Knight, indeed, from several experiments deduces the following propositions, which he offers, not so much to explain the nature of the cause of magnetism, as the manner in which it acts: the magnetic matter of a loadstone, he says, moves in a stream from one pole to the other internally, and is then carried back in a curve line externally, till it arrive again at the pole where it first entered, to be again admitted: the immediate cause why two or more magnetical bodies attract each other, is the flux of one and the same stream of magnetical matter through them; and the immediate cause of magnetic repulsion, is the conflux and accumulation of the magnetic matter. Philos. Trans. vol. 44, pa. 665. Mr. Michell rejects the motion of a subtile fluid; but though he proposed to publish a theory of magnetism established by experiments, no such theory ever appeared.

Signor Beccaria, from observing that a sudden stroke of lightning gives polarity to magnets, conjectures, that a regular and constant circulation of the whole mass of the electric fluid, from north to south, may be the original cause of magnetism in general. But this current he does not suppose to arise from one source, but from several, in the northern hemisphere of the earth: the aberration of the common centre of all the currents from the north point, may be the cause of the variation of the needle; the period of this declination of the centre of the currents, may be the period of the variation; and the obliquity with which the currents strike into the earth, may be the cause of the dipping of the needle, and also why bars of iron more easily receive the magnetic virtue in one particular direction. Lettre dell' Elettricismo, pa. 269; or Priestley's Hist. Elec. vol. 1, pa. 409. See also Cavallo's Treatise on Magnetism, and the article Variation in this volume.

MAGNIFYING, is the making of objects appear larger than they usually and naturally appear to the eye; whence convex lenses, which have the power of doing this, are called Magnifying Glasses.

The magnifying power of dense mediums of certain figures, was known to the ancients; though they were far from understanding the cause of this effect. Seneca says, that small and obscure letters appear larger and brighter through a glass globe filled with water; and he absurdly accounts for it by saying, that the eye slides in the water, and cannot lay hold of its object. And Alexander Aphrodisensis, about two centuries after Seneca, says, that the reason why apples appear large when immersed in water, is, that the water which is contiguous to any body is affected with the same quality and colour; so that the eye is deceived in imagining the body itself larger. But the first distinct account we have of the magnifying power of glasses, is in the 12th century, in the writings of Roger Bacon, and Alhazen; and it is not improbable that from their observations the construction of spectacles was derived. In the Opus Majus of Bacon, it is demonstrated, that if a transparent body, interspersed between the eye and an object, be convex towards the eye, the object will appear magnified.

Magnifying *Glass*, in Optics, is a small spherical convex lens; which, in transmitting the rays of light, inflects them more towards the axis, and so exhibits objects viewed through them larger than when viewed by the naked eye. See Microscope.

MAGNITUDE, any thing made up of parts locally extended, or continued; or that has several dimensions; as a line, surface, solid, &c. Quantity is often used as synonymous with magnitude. See Quantity.

Geometrical Magnitudes, are usually, and most properly, considered as generated or produced by motion; as lines by the motion of points, surfaces by the motion of lines, and solids by the motion of surfaces.

Apparent Magnitude, is that which is measured by the optic or visual angle, intercepted between rays drawn from its extremes to the centre of the pupil of the eye. It is a fundamental maxim in optics, that whatever things are seen under the same or equal angles, appear equal; and vice versa.—The apparent magnitudes of an object, at different distances, are in a ratio less than that of their distances reciprocally.

The apparent magnitudes of the two great luminaries, the sun and moon, at rising and setting, are a phenomenon that has greatly embarrassed the modern philosophers. According to the ordinary laws of vision, they should appear the least when nearest the horizon, being then farthest from the eye; and yet it is found that the contrary is true in fact. Thus, it is well known that the mean apparent diameter of the moon, at her greatest height in the meridian, is nearly 31' in round numbers, subtending then an angle of that quantity as measured by any instrument. But, being viewed when she rises or sets, she seems to the eye as two or three times as large as before; and yet when measured by the instrument, her diameter is not found increased at all, but diminished.

Ptolemy, in his Almagest, lib. 1, cap. 3, taking for granted, that the angle subtended by the moon was really increased, ascribed the increase to a refraction of the rays by vapours, which actually enlarge the angle under which the moon appears, just as the angle is enlarged by which an object is seen from under water: and his commentator Theon explains distinctly how the dilatation of the angle in the object immersed in water is caused. But it being afterwards discovered, that there is no alteration in the angle, another solution was started by the Arab Alhazen, which was followed and improved by Bacon, Vitello, Kepler, Peckham, and others. According to Alhazen, by sight we apprehend the surface of the heavens to be flat, and judge of the stars as of ordinary visible objects extended on a wide plain; the eye sees them under equal angles indeed, but withal perceives a difference in their distances, and (on account of the semidiameter of the earth, which is interposed in one case, and not in the other) it is hence induced to judge those that appear more remote to be greater. Further improvement was made in this explanation by Mr. Hobbes, though he fell into some mistakes in his application of geometry to this subject: for he observes, that this deception operates gradually from the zenith to the horizon; and that if the apparent arch of the sky be divided into any number of equal parts, those parts, in descending towards the horizon, will subtend an angle that is gradually less and less. And he was the first who expressly considered the vaulted appearance of the sky as a real portion of a circle.

Descartes, and from him Dr. Wallis, and most other authors, account for the appearance of a different distance under the same angle, from the long series of objects interposed between the eye and the extremity of the sensible horizon; which makes us imagine it more remote than when in the meridian, where the eye sees nothing in the way between the object and itself. This idea of a great distance makes us imagine the luminary the larger; for an object being seen under any certain angle, and believed at the same time very remote, we naturally judge it must be very large, to appear under such an angle at such a distance. And thus a pure judgment of the mind makes us see the sun, or the moon, larger in the horizon than in the meridian; notwithstanding their diameters measured by any instrument are really less in the former situation than the latter.

James Gregory, in his Geom. Pars Universalis, pa. 141, subscribes to this opinion: Father Mallebranche also, in the first book of his Recherche de la Vérité, has explained this phenomenon almost in the expression of Descartes: and Huygens, in his Treatise on the Parhelia, translated by Dr. Smith, Optics, art. 536, has approved, and very clearly illustrated, the received opinion. The cause of this fallacy, says he, in short, is this; that we think the sun, or any thing else in the heavens, farther from us when it is near the horizon, than when it approaches towards the vertex, because we imagine every thing in the air that appears near the vertex to be farther from us than the clouds that fly over our heads; whereas, on the other hand, we are used to observe a large extent of land lying between us and the objects near the horizon, at the farther end of which the convexity of the sky begins to appear; which therefore, with the objects that appear in it, are usually imagined to be much farther from us. Now when two objects of equal magnitude appear under the same angle, we always judge that object to be larger which we think is remoter. And this, according to them, is the true cause of the deception in question.

Gassendus was of opinion, that this effect arises from hence; that the pupil of the eye, being always more open as the place is more dark, as in the morning and evening, when the light is less, and besides the earth being then covered with gross vapours, through a longer column of which the rays must pass to reach the horizon; the image of the luminary enters the eye at a greater angle, and is really painted there larger than when the luminary is higher. See APPARENT *Diameter* and *Magnitude*.

F. Gouge advances another hypothesis, which is, that when the luminaries are in the horizon, the proximity of the earth, and the gross vapours with which they then appear enveloped, have the same effect with regard to us, as a wall, or other dense body, placed behind a column; which in that case appears larger than when insulated, and encompassed on all sides with an illuminated air.

The commonly received opinion has been disputed, not only by F. Gouge, who observes, Acad. Sci. 1700, pa. 11, that the horizontal moon appears equally large across the sea, where there are no objects to produce the effect ascribed to them; but also by Mr. Molyneux, who says, Philos. Trans. Abr. vol. 3, pa. 365, that if this hypothesis be true, we may at any time increase the apparent magnitude of the moon, even in the meridian; for, in order to divide the space between it and the eye, we need only to look at it behind a cluster of chimneys, the ridge of [illegible] or the top of a house, &c. He makes also the sam[e ob]servation with F. Gouge, above mentioned, and f[urther] observes, that when the height of all the intermedia[te ob]jects is cut off; by looking through a tube, the im[agina]tion is not helped, and yet the moon seems still as la[rge as] before.

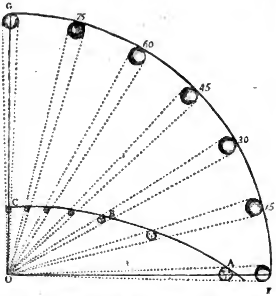
M. Biot, however, in his treatise of Physical Astro[nomy] seems to be of a contrary opinion, for he says, that a[s soon] as the moon is viewed through a tube, or even thro[ugh a] small hole pierced in a card, so as to take off the vi[ew of] intervening objects, the deception ceases; and the d[iame]ter appears no larger than when it is observed in th[e ze]nith.

Bishop Berkeley supposed, that the moon appears l[arger] near the horizon, because she then appears fainter [and] her beams affect the eye less. And Mr. Robins has [pain]fully recited some other opinions on this subject, [Math.] Tracts, vol. 2, pa. 242, &c.

Dr. Desaguliers has illustrated the doctrine of th[e ho]rizontal moon, Philos. Trans. Abr. vol 8, pa. 105, o[n the] supposition of our imagining the visible heavens to be a small portion of a spherical surface, and consequ[ently] supposing the moon to be farther from us in the ho[rizon] than near the zenith; and by several ingenious co[ntri]vances he demonstrated how liable we are to such d[ecep]tions. The same idea is pursued still further b[y Dr.] Smith, in his Optics, where he determines, that the c[entre] of the apparent spherical segment of the sky lying [far] below the eye, or the horizon, the apparent distan[ce of] its parts near the horizon was about 3 or 4 times gr[eater] than the apparent distance of its parts over head; [for] which reason it is, he infers, that the moon always ap[pears] the larger as she is lower, and also that we always [judge] the height of a celestial object to be more than it r[eally] is. Thus, he determined, by measuring the actual h[eight] of some of the heavenly bodies, when to his eye [they] seemed to be half way between the horizon and the ze[nith,] that their real altitude was then only 23°: when the [sun] was about 30° high, the upper portion always appe[ared] less than the under; and he thought that it was consi[derably] greater when the sun was 18° or 20° high. Mr. Ro[bins,] in his Tracts, vol. 2, pa. 245, shows how to determine [the] apparent concavity of the sky in a more accurate [and] geometrical manner; by which it appears, that if the [alti]tude of any of the heavenly bodies be 20°, at the [time] when it seems to be half way between the horizon an[d the] zenith, the horizontal distance will be hardly less th[an 3] times the perpendicular distance; but if that altitude [be] 28°, it will be little more than 2 and a half.

Dr. Smith, having determined the apparent figu[re of] the sky, thus applies it to explain the phenomeno[n of] the horizontal moon, and other similar appearances i[n the] heavens. Suppose the arc ABC to represent the appa[rent] concavity of the heavens: then the diameter of the [sun] and moon would seem to be greater in the horizon t[han] at any altitude, measured by the angle AOB, in the r[atio] of its apparent distances, AO, BO. The numbers [which] express these proportions he reduced into the anne[xed] table, answering to the corresponding altitudes of the [sun] or moon, which are also exactly represented to the ey[e in] the figure, in which the moon, placed in the quadra[ntal] arc FG described about the centre O, are all equal to e[ach] other, and represent the body of the moon in the heig[hts] there noted, and the unequal moons in the concavity [...]

are terminated by the visual rays coming from the circumference of the real moon, at those heights to the eye, at o.



Dr. Smith also observes, that the apparent concave of the sky, being less than a hemisphere, is the cause that the breadths of the colours in the inward and outward rainbows, and the interval between the bows, appear least at the top, and greater at the bottom.

This theory of the horizontal moon is also confirmed by the appearances of the tails of comets, which, whatever be their real figure, magnitude, and situation, in absolute space, do always appear to be an arc of the concave of the heavens. Dr. Smith however justly acknowledges that, at different times, the moon appears of very different magnitudes, even in the same horizon, and occasionally of an extraordinary large size; which he is not able to give a satisfactory explanation of. Smith's Optics, vol. 1, pa. 63, &c, Remarks, pa. 53.

MAIGNAN (Emanuel), a religious minim, and one of the greatest philosophers of his age, was born at Thoulouse in 1601. Like the famous Pascal, he became a complete mathematician without the assistance of a teacher; and filled the professor's chair at Rome in 1636, where, at the expense of Cardinal Spada, he published his book De Perspectiva Horaria, in 1648. Maignan returned to Thoulouse in 1650, and was created Provincial. His knowledge in mathematics, and physical experiments, was very early known; especially from a dispute which arose between him and father Kircher, about a catoptrical invention.

The king, who in 1660 amused himself with the machines and curiosities in the father's cell, made him offers by Cardinal Mazarin, to draw him to Paris; but he humbly desired to spend the remainder of his days in a cloister.—He published a Course of Philosophy, in 4 volumes 8vo, at Thoulouse, in 1652; to the second edition of which, in folio, 1673, he added two treatises; the one against the vortices of Descartes, the other on the speaking-trumpet invented by Sir Samuel Morland.—He also formed a machine, which showed, by its movements, that Descartes's supposition concerning the manner in which the universe was formed, or might have been formed, and concerning the centrifugal force, was entirely without foundation.

Thus this great philosopher and divine passed a life of tranquillity, in writing books, making experiments, and reading lectures. He was frequently consulted by the most eminent philosophers on different subjects, which he answered either by writing or otherwise; and no person was certainly more industrious: it is said that he even studied in his sleep; for his very dreams employed him in problems, which he pursued sometimes till he came to a solution or demonstration; and he has frequently been awaked out of his sleep of a sudden, by the exquisite pleasure which he felt on discovery of it. The excellence of his manners, and his unspotted virtues, rendered him no less worthy of esteem, than his genius and learning.—It is said that he composed with great ease, and without making any alterations. He died at Thoulouse in 1676, at 75 years of age.

MALLEABLE, the property of a solid ductile body, from which it may be beaten, forged, and extended under the hammer, without breaking, which is a property of all metals.

MANFREDI (Eustachio), a celebrated atsronomer and mathematician, born at Bologna in 1674. His genius was always above his age: for he was a tolerable poet and wrote ingenious verses while he was but a child: and while very young he formed in his father's house an academy of youth of his own age, who became there the Academy of Sciences, or the Institute. He was professor of mathematics at Bologna in 1698, and superintendant of the waters there in 1704. The same year he was placed at the head of the College of Montalte, founded at Bologna for young men intended for the church: and in 1711 he obtained the office of astronomer to the Institute of Bologna. He became member of the Academy of Sciences of Paris in 1726, and of the Royal Society of London in 1729; and died the 15th of February 1739, at 65 years of age.—His works are:

1. Ephemerides Motuum Cœlestium ab anno 1715 ad annum 1750; 4 volumes in 4to.—The first volume is an excellent introduction to astronomy; and the other three contain numerous calculations. His two sisters greatly assisted him in composing this work.

2. De Transitu Mercurii per Solem, anno 1723. Bologna 1724, in 4to.

3. De Annuis Inerrantium Stellarum Aberrationibus, Bologna 1729, in 4to.—Besides a number of papers in the Memoirs of the Academy of Sciences, and in other places.

MANILIUS (Marcus), a Latin astronomical poet, who lived in the reign of Augustus Cæsar. He wrote an ingenious poem relating to the stars and the sphere, called Astronomicon; which, not being mentioned by any of the ancient poets, was unknown, till about two centuries since, when it was found buried in some German library, and published by Poggius. There is no account to be found of this author, but what can be drawn from his poem; which contains a system of the ancient astronomy and astrology, together with the philosophy of the Stoics. It consists of five books; though there was a sixth, which has not been recovered. In this work, Manilius hints at some opinions, which later ages have been ready to glory in as their own discoveries. Thus he defends the fluidity of the heavens, against the hypothesis of Aristotle; and asserts that the fixed stars are not all in the same concave superficies of the heavens, and equally distant from the centre of the world: he maintains that they are all of the same nature and substance with the sun, and that each of them has a particular vortex of its own: and lastly, he says that the milky way is only the united lustre of a great many small imperceptible stars; which indeed the moderns now see to be such through their telescopes. The best editions of Manilius are that of Joseph Scaliger, in 4to, 1600; that of Bentley, in 4to, 1738, and that of Edmund Burton, esq. in 8vo, 1783.

MANOMETER, or MANOSCOPE, an instrument to show or measure the alterations in the rarity or density of the air.—The manometer differs from the barometer in this, that the latter only serves to measure the Weight of the atmosphere, or of the column of air over it; but the former, the Density of the air in which it is found; which density depends not only on the weight of the atmosphere, but also on the action of heat and cold, &c. Authors however often confound the two together; and Mr. Boyle himself has given a very good manometer of his contrivance, under the name of a Statical Barometer, consisting of a bubble of thin glass, about the size of an orange, which being counterpoised when the air was in a mean state of density, by means of a nice pair of scales, sunk when the atmosphere became lighter, and rose as it grew heavier.

The manometer used by Captain Phipps, in his voyage towards the north pole, consisted of a tube of a small bore, with a ball at the end. The barometer being at 29·7, a small quantity of quicksilver was put into the tube, to take off the communication between the external air, and that confined in the ball and the part of the tube below this quicksilver. A scale is placed on the side of the tube, which marks the degrees of dilatation arising from the increase of heat in this state of the weight of the air, and has the same graduation as that of Fahrenheit's thermometer, the point of freezing being marked 32. In this state therefore it will show the degrees of heat in the same manner as a thermometer. But when the air becomes lighter, the bubble inclosed in the ball, being less compressed, dilates itself, and occupies a space as much larger as the compressing force is less; therefore the changes arising from the increase of heat, are proportionably larger; and the instrument shows the differences in the density of the air, arising from the changes in its weight and heat. Mr. Ramsden found, that a heat equal to that of boiling water, increased the magnitude of the air, from what it was at the freezing point, by $\frac{414}{1000}$ of the whole. Hence it follows, that the ball and the part of the tube below the beginning of the scale, is of a magnitude equal to almost 414 degrees of the scale. If the height of both the manometer and thermometer be given, the height of the barometer may be thence deduced, by this rule:

as the height of the manometer increased by 414,
to the height of the thermometer increased by 414,
so is 29·7, to the height of the barometer;

or if m denote the height of the manometer, and t the height of the thermometer; then

$m + 414 : t + 414 :: 29·7 : \frac{t + 414}{m + 414} \times 29·7$, which is the height of the barometer.

Another kind of manometer was made use of by C Roy, in his attempts to correct the errors of the meter; which is described in the Philos. Trans. v pa. 689.

MANTELET, a kind of moveable parapet, or s of about 6 feet high, set upon trucks or little wheel guided by a long pole; so that in a siege it may be before the pioneers, and serve as blinds, or scree shelter them from the enemy's small shot. Mantel made of different materials, so as to render them n proof; some consisting of strong boards nailed tog and covered with tin; or of thick leather, or of lay rope, &c, firmly bound together.

There are also other kinds of mantelets, cover the top, used by the miners in approaching the wa works of an enemy. The double mantelets form an and stand square, making two fronts. It appears Vegetius, that mantelets were in use among the anc under the name of Vineæ.

MAP, a plane figure representing the surface c earth, or some part of it on a plane; being a projecti the globular surface of the earth, exhibiting coun seas, rivers, mountains, cities, &c, in their due posi or nearly so.

Maps are either universal or partial.

Universal MAPS are such as exhibit the whole su of the earth, or the two hemispheres.

Particular, or *Partial* MAPS, are those that exhibit particular region, or part of the earth.

Both kinds are usually called geographical, or l maps, as distinguished from hydrographical, or sea-m which represent only the seas and sea coasts, and are perly called Charts.

Anaximander, the scholar of Thales, it is said, a 400 years before Christ, first invented geographical tal or maps The Pentingerian Tables, published by Co lius Pentinger of Augsburg, contain an itinerary of whole Roman empire; all places, except seas, woods, deserts, being laid down according to their measured stances, but without any mention of latitude, longitud bearing.

The maps published by Ptolemy of Alexandria, ab the 144th year of Christ, have meridians and parallels, better to define and determine the situation of places, are great improvements on the construction of the m ancient maps. Though Ptolemy himself owns that maps were copied from some that were made by Mari Tirus, &c, with the addition of some improvements of own. But from his time till about the 14th centu during which geography and most sciences were neglect no new maps were published. Mercator was the first any note among the moderns, and next to him Orteli who undertook to make a new set of maps, with the n dern divisions of countries and names of places; for w of which, those of Ptolemy were become almost usel After Mercator, many others published maps, but for most part they were mere copies of his. Towards t middle of the 17th century, Bleau in Holland, and Sans in France, published new sets of maps, with many i provements from the travellers of those times, which we afterwards copied, with little variation, by the Englis French, and Dutch: but the best of these were those Vischer and Dewitt. And later observations have fu nished us with still more accurate and copious sets maps, by Delisle, Robert, Wells, &c, &c. Concerni maps, see Varenius's Geog. lib. 3, cap. 3, prop. 4; Fournier's Hydrog. lib. 4, cap. 24; Wolfius's Elem. Hydrog. cap. 9; John Newton's Idea of Navigation; Mead's Construction of Globes and Maps; Wright's Construction of Maps, &c, &c.

Construction of MAPS.—Maps are constructed by making a projection of the globe, either on the plane of some particular circle, or by the eye placed in some particular point, according to the rules of perspective, &c; of which there are several methods.

First, to construct a Map of the World, or a general Map.

1st *Method.*—A map of the world must represent two hemispheres; and they must both be drawn upon the plane of that circle which divides the two hemispheres. The first way is to project each hemisphere upon the plane of some particular circle, by the rules of orthographic projection, forming two hemispheres on one common base or circle. When the plane of projection is that of a meridian, the maps will be the east and west hemispheres, the other meridians will be ellipses, and the parallel circles will be right lines. On the plane of the equinoctial, the meridians will be right lines crossing in the centre, which will represent the pole, and the parallels of latitude will be circles having that common centre, and the maps will be the northern and southern hemispheres. The fault of this way of drawing maps is, that near the outside the circles are too near one another; and therefore equal spaces on the earth are represented by very unequal spaces on the map.

2d *Method.*—Another way is to project the same hemispheres by the rules of stereographic projection; in which way, all the parallels are represented by circles, and the meridians by circles or right lines. And here the contrary fault happens, viz, the circles towards the outsides are too far asunder, and about the middle they are too near together.

3d *Method.*—To remedy the faults of the two former methods, proceed as follows. First, for the east and west hemispheres, describe the circle PENQ for the meridian (pl. 21, fig. 1) or plane of projection; through the centre of which draw the equinoctial EQ, and axis PN perpendicular to it, making P and N the north and south pole. Divide the quadrants PE, EN, NQ, and QP into 9 equal parts, each representing 10 degrees, beginning at the equinoctial EQ: divide also CP and CN into 9 equal parts; beginning at EQ; and through the corresponding points draw the parallels of latitude. Again, divide CE and CQ into 9 equal parts; and through the points of division, and the two poles P and N, draw circles, or rather ellipses, for the meridians. So shall the map be prepared to receive the several places and countries of the earth.

Secondly, For the north or south hemisphere, draw AQBE, for the equinoctial (fig. 2), dividing it into the four quadrants EA, AQ, QB, and BE; and each quadrant into 9 equal parts, representing each 10 degrees of longitude; and then, from the points of division, draw lines to the centre C, for the circles of longitude. Divide any circle of longitude, as the first meridian EC, into 9 equal parts, and through these points describe circles from the centre C, for the parallels of latitude, numbering them as in the figure.

In this 3d method, equal spaces on the earth are represented by equal spaces on the map, as near as any projection will bear; for a spherical surface can no way be represented exactly on a plane. Then the several countries of the world, seas, islands, sea-coasts, towns, &c, are to be entered in the map, according to their latitudes and longitudes.

In filling up the map, all places representing land are filled with such things as the countries contain; but the seas are left blank; the shores adjoining to the sea being shaded. Rivers are marked by strong lines, or by double lines, drawn winding in form of the rivers they represent; and small rivers are expressed by small lines. Different countries are best distinguished by different colours, or at least the borders of them. Forests are represented by trees; and mountains shaded to make them appear as such. Sands are denoted by small points or specks; and rocks under water by a small cross. In any void space, draw the mariner's compass, with the 32 points or winds.

II. *To draw a Map of any particular Country.*

1st *Method.*—For this purpose its extent must be known, as to latitude and longitude; as suppose Spain, lying between the north latitudes 36 and 44, and extending from 10 to 23 degrees of longitude; so that its extent from north to south is 8 degrees, and from east to west 13 degrees.

Draw the line AB for a meridian passing through the middle of the country (fig. 3), on which set off 8 degrees from B to A, taken from any convenient scale; A being the north, and B the south point. Through A and B draw the perpendiculars CD, EF, for the extreme parallels of latitude. Divide AB into 8 parts, or degrees, through which draw the other parallels of latitude, parallel to the former.

For the meridians; divide any degree in AB into 60 equal parts, or geographical miles. Then, because the length of a degree in each parallel decreases towards the pole, from the table showing this decrease, under the article DEGREE, take the number of miles answering to the latitude of B, which is 48½ nearly, and set it from B, 7 times to E, and 6 times to F; so is EF divided into degrees. Again, from the same table take the number of miles of a degree in the latitude A, viz 43⅛ nearly; which set off, from A, 7 times to C, and 6 times to D. Then from the points of division in the line CD, to the corresponding points in the line EF, draw so many right lines, for the meridians. Number the degrees of latitude up both sides of the map, and the degrees of longitude on the top and bottom. Also, in some vacant place make a scale of miles; or of degrees, if the map represent a large part of the earth; to serve for finding the distances of places from each other.

Then make the proper divisions and subdivisions of the country: and knowing the latitudes and longitudes of the principal places, it will be easy to set them down in the map; for, any town, &c, must be placed where the circles of its latitude and longitude intersect. For instance, Gibraltar, whose latitude is 36° 11′, and longitude 12° 27′, will be at G: and Madrid, whose lat. is 40° 10′, and long. 14° 44′, will be at M. In like manner the mouth of a river must be set down; but to describe the whole river, the latitude and longitude of every turning must be marked down, and the towns and bridges by which it passes. And so for woods, forests, mountains, lakes, castles, &c. The boundaries will be described, by setting down the remarkable places on the sea-coast, and drawing a continued line through them all: which method is very proper for small countries.

2d *Method.*—Maps of particular places are but portions of the globe, and therefore may be drawn after the same manner as the whole is drawn: that is, such a map may be drawn either by the orthographic or stereographic projection of the sphere, as in the last prob. But in partial maps, an easier way is as follows. Having drawn the meridian AB (fig. 3), and divided it into equal parts as in the last method, through all the points of division draw lines perpendicular to AB, for the parallels of latitude; CD, EF being the extreme parallels. Then to divide these, set off the degrees in each parallel, diminished after the manner directed for the two extreme parallels CD, EF, in the last method: and through all the corresponding points draw the meridians, which will be curve lines; which were right lines in the last method; because only the extreme parallels were divided by the table. This method is proper for a large tract, as Europe, &c: in which case the parallels and meridians need only be drawn to every 5 or 10 degrees: and it is also much used in drawing maps; as all the parts are nearly of their due magnitude, but a little distorted towards the outside, from the oblique intersections of the meridians and parallels.

3d *Method.*—Draw PB of a convenient length, for a meridian; divide it into 9 equal parts, and through the points of division, describe as many circles for the parallels of latitude, from the centre P, which represents the pole. Suppose AB (fig. 4) the height of the map; then CD will be the parallel passing through the greatest latitude, and EF will represent the equator. Divide the equator EF into equal parts, of the same dimension as those in AB, both ways, beginning at B. Divide also all the parallels into the same number of equal parts, but lesser, in proportion to the numbers for the several latitudes, as directed in the last method for the rectilineal parallels. Then through all the corresponding divisions, draw curve lines, to represent the meridians, the extreme ones being EC and FD. Lastly, number the degrees of latitude and longitude, and place a scale of equal parts, either of miles or degrees, for measuring distances.—This is a very good way of drawing large maps, and is called the globular projection; all the parts of the earth being represented nearly of their due magnitude, excepting that they are a little distorted towards the outsides.

When the place which the map is to represent, is but small, as if a county was to be exhibited; the meridians, as to sense, will be parallel to one another, and the whole will differ very little from a plane. Such a map will be made more easily than by the preceding rules. It will here be sufficient to measure the distances of places in miles, and so lay them down in a plane rectangular map. But this belongs more properly to surveying.

The Use of MAPS is obvious from their construction. The degrees of the meridians and parallels show the latitudes and longitudes of places, and the scale of miles annexed, their distances; the situation of places, with regard to each other, as well as to the cardinal points, appears by inspection; the top of the map being always the north, the bottom the south, the right hand the east, and the left hand the west; unless the compass, usually annexed, show the contrary.

MARALDI (JAMES PHILIP), a learned astronomer and mathematician, was born in 1665, at Perinaldo in the county of Nice, a place already honoured by the birth of his maternal uncle the celebrated Cassini. Having made a considerable progress in mathematics, at the age of 22, his uncle who had been a long time settled in France, invited him there, that he might himself cultivate the promising genius of his nephew. Maraldi no sooner applied himself to the contemplation of the heavens, than he conceived the design of forming a catalogue of the fixed stars, the foundation of all the astronomical edifice. In consequence of this design, he applied himself to observe them with the most constant attention; and he became by this means so intimate with them, that on being shown any one of them, however small, he could immediately tell what constellation it belonged to, and its place in that constellation. He has been known to discover those small comets, which astronomers often take for the stars of the constellation in which they are seen, for want of knowing precisely what stars the constellation consists of, when others, on the spot, and with eyes directed equally to the same part of the heavens, could not for a long time see any thing of them.

In 1700 he was employed under Cassini in prolonging the French meridian to the northern extremity of France, and had no small share in completing it. He then set out for Italy, where Clement the 11th invited him to assist at the assemblies of the Congregation then sitting in Rome to reform the calendar. Bianchini also availed himself of his assistance to construct the great meridian of the Carthusian church in that city. And in 1718 Maraldi, with three other academicians, prolonged the French meridian to the southern extremity of that country. He was admitted a member of the Academy of Sciences of Paris in 1699, in the department of astronomy, and communicated to it a great multitude of papers, which are printed in their Memoirs, in almost every year from 1699 to 1729, and usually several papers in each of the years; for he was indefatigable in his observations of every thing that was curious and useful in the motions and phenomena of the heavenly bodies. As to the catalogue of the fixed stars, it was not quite completed by him: for just as he had placed a mural quadrant on the terrace of the observatory, to observe some stars towards the north and the zenith, he fell sick, and died the 1st of December 1729.

MARCH, *Martius*, the 3d month of the year, according to the common way of computing, and consists of 31 days. The sun enters the sign Aries about the 20th or 21st day of this month.—Among the Romans, March was the first month; and in some ecclesiastical computations, that order is still preserved. In England, before the alteration of the stile, March was the 1st month in order, the year always commencing with the 25th day of the month. It has been said that it was Romulus who first divided the year into months; to the first of which he gave the name of his supposed father Mars. It is observed by Ovid, however, that the people of Italy had the month of March before the time of Romulus; but that they placed it differently; some making it the third, some the 4th, some the 5th, and others the 10th month of the year.

MARINERS-COMPASS. See COMPASS.

MARINUS. See PROCLUS.

MARIOTTE (EDME), an eminent French philosopher and mathematician, was born at Dijon, and admitted a member of the Academy of Sciences of Paris in 1666. His works however are better known than his life. He was a good mathematician, and the first French philosopher who applied much to experimental physics. The law of the shock or collision of bodies, the theory of the pressure and motion of fluids, the nature of vision, and of the air, particularly engaged his attention. He carried into his philosophical researches, that spirit of scrutiny and investigation so necessary to those who would make any considerable progress in improvement. He died in 1684.—He communicated a number of curious and valuable papers to the Academy of Sciences, which were printed in the collection of their Memoirs dated 1666, viz, from volume 1 to volume 10. And all his works were collected into 2 volumes in 4to, and printed at Leyden in 1717.

MARS, one of the ancient seven primary planets, and the first of the superior ones, being placed immediately next above the earth. It is usually denoted by this character ♂, being a mark rudely formed from a man holding a spear protruded, representing the god of war of the same name.

The mean distance of Mars from the sun, is 1524 of those parts, of which the distance of the earth from the sun is 1000; his excentricity 142; and his real distance 145 millions of miles. The inclination of his orbit to the plane of the ecliptic, is 1° 52′; the length of his year, or the period of one revolution about the sun, is 686$\frac{23}{24}$ of our days, or 667$\frac{3}{4}$ of his own days, which are 40 minutes longer than ours, the revolution on his axis being performed in 24 hours 40 minutes. His mean diameter is 4444 miles; and the same seen from the sun is 11″: the inclination of the axis to his orbit 0° 0′; place of the aphelion ♍ 2° 24′; place of his ascending node ♉ 17° 3′; and his parallax, according to Dr. Hooke and Mr. Flamsteed, is scarce 30 seconds.

Dr. Hooke, in 1665, observed several spots in Mars; which having a motion, he concluded the planet turned round its centre. In 1666, M. Cassini observed several spots in the two faces or hemispheres of Mars, which he found made one revolution in 24 hours 40 minutes. These observations were repeated in 1670, and confirmed by Maraldi in 1704 and 1719: whence both the motion and period, or natural day, of that planet, were determined

In the Philos. Trans. for 1781, Dr. Herschel gave a series of observations on the rotation of this planet about its axis, from which he concluded that one mean sidereal rotation was between 24 h. 39 m. 5 sec. and 24 h. 39 m. 22 sec.; and in the Philos. Trans. for 1784, is given a paper by the same gentleman, on the remarkable appearances at the polar regions of the planet Mars, the inclination of its axis, the position of its poles, and its spheroidical figure; with a few hints relating to its real diameter and atmosphere, deduced from his observations taken from the year 1777 to 1783 inclusively. He also observed several remarkable bright spots near both poles, which had a small motion; and the results of his observations are as follow; viz,

" Inclination of axis to the ecliptic, 59° 22′.
The node of the axis is in ♓ 17° 47′.
Obliquity of the planet's ecliptic 28° 42′.
The point Aries on Mars's ecliptic answers to our ♐ 19° 28′.—The figure of Mars is that of an oblate spheroid, whose equatorial diameter is to the polar one, as 1355 to 1272, or as 16 to 15 nearly.—The equatorial diameter of Mars, reduced to the mean distance of the earth from the sun, is 9″ 8‴.—And the planet has a considerable, but moderate atmosphere, so that its inhabitants probably enjoy a situation in many respects similar to ours."—Mars always appears with a ruddy troubled light; owing, it is supposed, to the nature of his atmosphere, through which the light passes.—In the acronical rising of this planet, or when in opposition to the sun, it is 5 times nearer to us than when in conjunction with him; and therefore appears much larger and brighter than at other times.—Mars, having his light from the sun, and revolving round it, has an increase and decrease like the moon: it may also be observed almost bisected, when in the quadratures, or in perigæon; but is never seen cornicular, as the inferior planets.

MARTIN (Benjamin), was born in 1704, and became one of the most celebrated mathematicians and opticians of his time. He first taught a school in the country; but afterwards came up to London, where he read lectures on experimental philosophy for many years, and carried on a very extensive trade as an optician and globemaker in Fleet-street, till the growing infirmities of old age compelled him to withdraw from the active part of business. Trusting too fatally to what he thought the integrity of others, he unfortunately, though with a capital more than sufficient to pay all his debts, became a bankrupt. The unhappy old man, in a moment of desperation from this unexpected stroke, attempted to destroy himself; and the wound, though not immediately mortal, hastened his death, which happened the 9th of February 1782, at 78 years of age.

Mr M. had a valuable collection of fossils and curiosities of almost every species; which after his death were almost given away by public auction. He was indefatigable as an artist, and as a writer he had a very happy method of explaining his subject, and wrote with clearness, and even considerable elegance. He was chiefly eminent in the science of optics; but he was well skilled in the whole circle of the mathematical and philosophical sciences, and wrote useful books on every one of them; though he was not distinguished by any remarkable inventions or discoveries of his own. His publications were very numerous, and generally useful: some of the principal of them were as follow:

The Philosophical Grammar; being a View of the present State of Experimental Physiology, or Natural Philosophy, 1735, 8vo.—A new, complete, and universal System or Body of Decimal Arithmetic, 1735, 8vo.—The Young Student's Memorial Book, or Pocket Library, 1735, 8vo.—Description and Use of both the Globes, the Armillary Sphere and Orrery, Trigonometry, 1736, 2 vols. 8vo.—System of the Newtonian Philosophy, 1759, 3 vols.—New Elements of Optics, 1759—Mathematical Institutions, 1764, 2 vols.—Philologic and Philosophical Geography, 1759.—Lives of Philosophers, their Inventions, &c. 1764.—Young Gentleman and Lady's Philosophy, 1764, 3 vols.—Miscellaneous Correspondence, 1764, 4 vols.—Institutions of Astronomical Calculations, 3 parts, 1765.—Introduction to the Newtonian Philosophy, 1765.—Treatise of Logarithms.—Treatise on Navigation. Description and Use of the Air-pump.—Description of the Torricellian Barometer.—Appendix to the Use of the Globes.—Philosophia Britannica, 3 vols.—Principles of Pump-work.—Theory of the Hydrometer.—Description and Use of a Case of Mathematical Instruments.—Ditto of a Universal Sliding Rule.—Micrographia, on the Microscope.—Principles of Perspective.—Course of Lectures.—Optical Essays.—Essay on Electricity.—Essay on Visual Glasses or Spectacles.—Horologia Nova, or New Art of Dialling.—Theory of Comets.—Nature and Construction of Solar Eclipses.—Venus in the Sun.—The Mariner's Mirror.—Thermometrum Magnum—Survey of the Solar System.—Essay on Island Chrystal.—Logarithmologia Nova, &c. &c.

MASKELYNE (Nevil), D. D. F. R. S. Astronomer Royal, &c, was born in London, on the 6th of October 1732, of an ancient family, which had been long established in the west of England. At 9 years of age he was placed at Westminster school, where his diligence speedily distinguished him. He acquired an early taste for astronomy and optics; but it was the solar eclipse of 1748 which decided his vocation. Perceiving how necessary the mathematics were, in the course he proposed to take, he determined on the study of them, and acquired in a few months the elements of geometry and algebra. This first success was the earnest of what he could not avoid obtaining, by reading the chief works on astronomy and the higher analysis, which he habitually studied. About this time he went to Cambridge, and entered in Catharine-hall, but afterwards in Trinity-college, where he received, with applause, the degree of bachelor of arts.

In 1755, he accepted of a curacy in the vicinity of London, where he resided some years, employing his leisure time in his favourite study. This situation also facilitated his acquaintance with the then astronomer-royal Bradley, for whom it appears that he made some calculations of importance. In 1758, he became fellow of Trinity-college, Cambridge, and the next year a fellow of the Royal Society.

But it was in the year 1761 that his real astronomical career began, when he was chosen to go to the island of St. Helena, to observe the transit of Venus over the sun's disk, and the parallax of the star Sirius, which had often been observed by Lacaille at the Cape of Good Hope. From calculating these observations, Dr. M. thought he saw proofs for the existence of a parallax of 4"½.

Clouds prevented the observation of the transit of Venus, the first object of the voyage. But being furnished with an excellent pendulum clock of Shelton's, which had been regulated at Greenwich by Dr. Bradley, he determined the number of oscillations which it made less at St. Helena than at London, in order thence to deduce the diminution of gravity.

The secondary object of the voyage, the parallax of Sirius also failed, through the fault of the suspension of the plumb-line, by a loop from the neck of a central pin; which had likewise been the fault of Lacaille's instrument. This disappointment gave occasion to an improvement in the construction of these astronomical instruments. Several other observations however in part indemnified Dr. M. for those disappointments; such as the observation of the tides at St. Helena, the variation of the compass, and the moon's horary parallaxes, &c. Also, in going out and returning home, he practised the method of finding the longitude by the lunar distances taken with a Hadley's quadrant, making out rules for the use of the seamen, and taught the method to the officers on board the ship. The same he afterwards explained in a letter to Dr. Birch, the secretary to the Royal Society, which was inserted in the Philos. Trans. vol. 52, for the year 1762; and still more fully in the British Mariner's Guide, which he published soon after his return from St. Helena, and which contained, among various new and practical articles in nautical astronomy, rules and examples for working the lunar observations.

In 1763, Dr. Maskelyne went to the island of Barbadoes, to settle the longitude of the place, and compare Mr. Harrison's watch with the time there, when he should arrive at the island with it. In this voyage also, Dr. M. tried observations on board of ship with Irwin's marine chair, which was found not to answer the purpose. Dr. M. made also several other astronomical observations, and among the rest, many relating to the moon's horary parallaxes. See Astronomical Observations at St. Helena and Barbadoes, in the Philos. Trans. vol. 54. Dr. M. returned from Barbadoes in the autumn of 1764, and made the report on Mr. H's watch, which, though favourable in general to the celebrated artist, was far from satisfying Mr. H. who attacked him in a pamphlet, to which Dr. M. wrote a reply.

In 1765, Dr. M. succeeded Mr. Bliss, as astronomer-royal at Greenwich Observatory, where for 47 years he diligently watched the heavens, and rendered innumerable benefits to the nation, as well as to individuals, in all the arts and sciences connected with astronomy and navigation. Immediately on his appointment to that office, he recommended the lunar method of finding the longitude to the Board of Longitude, and proposed to them to cause a nautical almanac to be calculated, and published, to facilitate the method; which they agreed to; the first of which was published for 1767, and which was continued under his direction, with the greatest credit, through 48 successive years. He also published a useful collection of tables requisite to be used with the nautical almanacs; as well as edited or encouraged the publication of other works, of like accessory usefulness; as, Taylor's Logarithms, the improved lunar tables of Mayer, and Mason, &c, &c. He procured also, at the expense of the Royal Society, the regular publication of all his own astronomical observations, made at the Observatory, forming a vast body of valuable matter, in 4 large folio volumes.

Dr. M. thus continued indefatigable in making observations for 47 years, hardly ever quitting the Observatory, except once a-week, in attending the meetings of the Royal Society one part of the year. In 1769, he remained in it to observe the transit of Venus, and he drew up instructions for the astronomers sent out by Great Britain to different countries. He collected their observations, and deduced from them the sun's parallax, and his distance from the earth. At his observatory, he made many of the most interesting and most difficult observations himself, as those of the moon; but necessarily confided to his assistant, those which were less essential and more easy. He followed closely the methods established by his celebrated predecessor Bradley, whom he even surpassed in the exactness of his daily observations. He brought to perfection Flamsteed's method of determining, at once, the right ascensions of stars and of the sun. He gave a catalogue of stars, not numerous indeed, but determined with particular care, which has served almost solely, during these thirty years, for the foundation of all astronomical researches.

Dr. M. did not publish much himself, being otherwise more usefully employed on his observations: but he was the cause and promoter of many publications by others. He corresponded with almost all the astronomers and philosophers in the world; and he was the medium of many of their communications to the Royal Society. The writings he produced, are remarkable for just ideas and an enlightened criticism. Such is a Dissertation on the

Equation of Time, where he has delicately noticed a mistake of Lacaille, and another less important mistake of Lalande. Some doubts having been raised, respecting the difference in latitude and longitude between the observatories of Greenwich and Paris, Dr. M., to whom the observations were sent, showed, with his usual moderation, that the doubts were improper; but he did not oppose the methods proposed to obviate them.

It was owing to the exertions of Dr. M., that a very satisfactory experiment was made to ascertain the general attraction of matter, and the medium density of all the matter in the earth. By a memoir presented to the Royal Society, he recommended it to that body, to try the experiment on the attraction of some hill in the British dominions. A convenient one having been found, viz, the Mountain Schihallien in Scotland, at the request of the Society, Dr. M. himself repaired to the place, and superintended the necessary measurements and observations, with his usual attention and correctness. His survey furnished the just plan and numerous sections of the hill, and his zenith sector showed 5″·8 for the mean deviation of the plumb-line by the attraction. From these materials it was, that the laborious calculations of Dr. Hutton showed, for the first time, that the mean density of the whole earth was about 5 times the density of water, a determination most likely very near the truth.

Dr. M. was particularly attentive to the care of his instruments, and made many improvements in them, and the modes of employing them. He greatly improved the suspension of the plumb-line of the zenith sectors. He contrived a micrometer composed of a prism, which moves according to the axis of the telescope. He made the eye-piece moveable, in order to avoid all parallax in bringing the eye opposite to each of the five wires, which the star passes in succession. He discovered also the inconvenience of narrow openings, used in all observatories: he enlarged the size of those at Greenwich, after having shown the necessity of placing the telescopes as much as possible in the open air: besides many more optical and mechanical improvements.

Dr. M. had good church preferment from his college; and his paternal estates, of which he was the last male heir, were also considerable. Having experienced a gradual decline of his health for some months, he at length expired on the 9th of Februay 1811, in the 79th year of his age; leaving a widow and daughter, as also his sister, the relict of Robert, late Lord Clive.

The principal works which Dr. M. left, besides his 4 vols. in folio of observations, the memoirs before noticed, and the first 48 volumes of the Nautical Almanac, calculated under his direction, and revised by him, are, his British Mariner's Guide; the Tables requisite for the Usage of the Nautical Almanac; Dissertations on Nautical Astronomy and the Use of the Octant; with at least 30 learned memoirs presented to the Royal Society, and printed in the Philos. Transactions, between the years 1762 and 1794; and finally, his posthumous works, of the contents of which we are as yet ignorant, but which astronomers will be very anxious to receive from the hands of Professor Vince, to whose care it seems they have been left. Indeed it would be well becoming the respect of his relict, to cause a collected and uniform edition of all his works to be made, for the honour of his memory and the greater convenience of the scientific public.

Thus we have described the philosopher: but the man, the father, the friend, was not less valuable. Every astronomer, every philosopher, found in him a brother. Of a character friendly and amiable, he gained the affections of all those who had the good fortune to know him, and his death was honoured with their regret.

MASS.—The quantity of matter in any body. This is rightly estimated by its weight; whatever be its figure, or whether its bulk or magnitude be large or small.

MATERIAL, relating to Matter.

MATHEMATICAL, relating to Mathematics.

MATHEMATICAL *Sect*, is one of the two leading philosophical sects, which arose about the beginning of the 17th century; the other being the metaphysical sect. The former directed its researches by the principles of Gassendi, and sought after truth by observation and experience. The disciples of this sect denied the possibility of erecting on the basis of metaphysical and abstract truths, a regular and solid system of philosophy, without the aid of assiduous observation and repeated experiments, which are the most natural and effectual means of philosophical progress and improvement. The advancement and reputation of this sect, and of natural knowledge in general, were much owing to the plan of philosophizing proposed by Lord Bacon, to the establishment of the Royal Society in London, to the genius and industry of Mr. Boyle, and to the unparalleled researches and discoveries of Sir Isaac Newton. Barrow, Wallis, Locke, and many other great luminaries in learning also adorned this sect.

MATHEMATICS, the science of quantity; or a science that considers magnitudes either as computable or measurable. The word in its original, *μαθησις*, *mathesis*, signifies Discipline or Science in general; and, it seems, has been applied to the doctrine of quantity, either by way of eminence, or because, this being the first of all other sciences, the rest took their common name from it. As to the origin of the mathematics, Josephus dates it before the flood, and makes the sons of Seth observers of the course and order of the heavenly bodies: he adds, that to perpetuate their discoveries, and secure them from the injuries either of a deluge or a conflagration, they had them engraven on two pillars, the one of stone, the other of brick; the former of which, he says, was yet standing in Syria in his time.

Indeed it is pretty generally agreed that the first cultivators of mathematics, after the flood, were the Assyrians and Chaldeans; from whom, Josephus adds, the science was carried by Abraham to the Egyptians; who became so celebrated for their knowledge, that Aristotle even fixes the first rise of mathematics among them. From Egypt, 584 years before Christ, mathematics passed into Greece, being carried thither by Thales; who having learned geometry of the Egyptian priests, taught it in his own country. After Thales, came Pythagoras; who, among other mathematical arts, paid a particular regard to arithmetic; drawing the greatest part of his philosophy from numbers. He was the first, according to Laertius, who abstracted geometry from matter; and to him we owe the doctrine of incommensurable magnitude, and the five regular bodies, besides the first principles of music and astronomy. To Pythagoras succeeded Anaxagoras, Oenopides, Briso, Antipho, and Hippocrates of Scio; all of whom particularly applied themselves to the quadrature of the circle, the duplication of the cube, &c; but the efforts of the latter were the most successful: he is also mentioned by Proclus, as the first who compiled elements of mathematics.

Democritus excelled in mathematics as well as physics; though none of his works in either kind are extant; the destruction of which is by some authors ascribed to Aristotle. The next in order is Plato, who not only improved geometry, but introduced it into physics, and so laid the foundation of a solid philosophy. From his school arose a number of mathematicians. Proclus mentions 13 of note; among whom was Leodamus, who improved the analysis first invented by Plato; Theætetus, who wrote Elements; and Archytas, who has the credit of being the first that applied mathematics to the useful purposes of life. These were succeeded by Neocles and Theon, the last of whom contributed to the elements. Eudoxus excelled in arithmetic and geometry, and was the first founder of a system of astronomy. Menechmus invented the conic sections, and Theudius and Hermotimus improved the elements.

For Aristotle, his works are so stored with mathematics, that Blancanus compiled out of them an entire book on mathematics. Eudemus and Theophrastus were of this school; the first of whom wrote upon numbers, geometry, and invisible lines; and the latter composed a mathematical history. To Aristeus, Isidorus, and Hypsicles, we owe the books of Solids; which, with the other books of Elements, were improved, collected, and methodised by Euclid, who died 284 years before the birth of Christ.

A hundred years after Euclid, Eratosthenes and Archimedes became celebrated for their extensive knowledge, particularly the latter, who was contemporary with Conon, a geometrician and astronomer. Soon after which flourished Apollonius Pergæus, whose excellent treatise on conics is still extant. To him are also ascribed the 14th and 15th books of Euclid, and which, it is said, were contracted by Hypsicles. Hipparchus and Menelaus wrote on the subtenses of the arcs in a circle; and the latter also on spherical triangles. Theodosius's 3 books of Spherics are still extant. All these authors, Menelaus excepted, lived before Christ.

Ptolemy of Alexandria, a celebrated geometrician, and the prince of astronomers, was born about 70 years after Christ. To him succeeded the philosopher Plutarch, some of whose mathematical problems are still extant. After him, in the order of time, was Eutocius, who commented on Archimedes, and occasionally mentions the inventions of Philo, Diocles, Nicomedes, Sporus, and Heron, on the duplication of the cube. To Ctesebes of Alexandria we are indebted for pumps; and Geminus, who lived soon after, is preferred by Proclus to Euclid himself.

Diophantus of Alexandria was a great master of numbers, and the first Greek writer on algebra that we know of. Among others of the ancients, Nicomachus is celebrated for his arithmetical, geometrical, and musical works: Serenus, for his books on the section of the cylinder: Proclus, for his commentaries on Euclid; and Theon, who has been said to be the author of the books of Elements ascribed to Euclid. The last to be named among the ancients, is Pappus of Alexandria, who flourished about the year of Christ 400, and is justly celebrated for his books of Mathematical Collections, still extant.

Mathematics are commonly distinguished into speculative and practical, pure and mixed.

Speculative MATHEMATICS, is that which barely contemplates the properties of things: and

Practical MATHEMATICS, that which applies the knowledge of those properties to some useful purposes.

Pure MATHEMATICS is that branch which considers quantity abstractedly, and without any relation to matter or bodies.

Mixed MATHEMATICS considers quantity as subsisting in material beings; for instance, length in a pole, depth in a river, height in a tower, &c.

Pure Mathematics, again, either considers quantity as discrete, and so computable, as arithmetic; or as concrete, and so measurable, as geometry.

Mixed Mathematics are very extensive, and are distinguished by various names, according to the different subjects it considers, and the different views in which it is taken; such as astronomy, geography, optics, hydrostatics, navigation, &c, &c.

Pure mathematics has one peculiar advantage, that it occasions no contests among wrangling disputants, as is the case in other branches of knowledge: and the reason is, because the definitions of the terms are premised, and every person that reads a proposition has the same idea of every part of it. Hence it is easy to put an end to all mathematical controversies, by showing, either that our adversary is not constant with his definitions, or has not established the true premises, or that he has drawn false conclusions from true principles; and in case we are not able to do either of these, we must acknowledge the truth of what he has proved. It is true, that in mixed mathematics, where we reason mathematically upon physical subjects, such just definitions cannot be given as in geometry: we must therefore be content with descriptions; which will be of the same use as definitions, provided we be consistent with ourselves, and always mean the same thing by those terms we have once explained.

Dr. Barrow gives a very elegant description of the excellence and usefulness of mathematical knowledge, in his inaugural oration, on being appointed professor of mathematics at Cambridge. The mathematics, he observes effectually exercise, not vainly delude, nor vexatiously torment studious minds with obscure subtleties, but plainly demonstrate every thing within their reach, draw certain conclusions, instruct by profitable rules, and unfold pleasant questions. These disciplines likewise enure and corroborate the mind to a constant diligence in study; they wholly deliver us from a credulous simplicity, most strongly fortify us against the vanity of scepticism, effectually restrain us from a rash presumption, most easily incline us to a due assent, and perfectly subject us to the government of right reason. While the mind is abstracted and elevated from sensible matter, distinctly views pure forms, conceives the beauty of ideas, and investigates the harmony of proportions; the manners themselves are sensibly corrected and improved, the affections composed and rectified, the fancy calmed and settled, and the understanding raised and excited to more divine contemplations.

For the history of mathematics, consult Wallis, Montucla, Kæstner, Bossut, Bailey, &c, and the names of its several branches in this Dictionary.

MATTER, an extended substance. Other properties of matter are, that it resists, is solid, divisible, moveable passive, &c: and it forms the principles of which all bo dies are composed. Matter and form, the two simple and original principles of all things, according to the ancients, composing some simple natures, which they called Elements; from the various combinations of which all natural things were afterwards composed.

Dr. Woodward was of opinion, that matter is originally and really various, being at its first creation divided into several ranks, sets, or kinds of corpuscles, differing in substance, gravity, hardness, flexibility, figure, size, &c; and from the various compositions and combinations of which, he thinks, arise all the varieties in bodies as to colour, hardness, gravity, tastes, &c. But it is Sir Isaac Newton's opinion, that all those differences result from the various arrangements of the same matter; which he accounts homogeneous and uniform in all bodies.

The quantity of matter in any body, is its measure arising from the joint consideration of the magnitude and density of the body: as, if one body be twice as dense as another, and also occupy twice the space, then will it contain 4 times the matter of the other. This quantity of matter is best discovered by the weight or gravity of the body, to which it is always proportional.

Newton observes, that "it seems probable, God, in the beginning, formed matter in solid, massy, hard, impenetrable, moveable particles, of such sizes, figures, and with such other properties, and in such proportion to space, as most conduced to the end for which he formed them; and that these primitive particles, being solid, are incomparably harder than any porous bodies compounded of them; even so very hard, as never to wear, and break in pieces: no ordinary power being able to divide what God himself made one in the first creation. While the particles continue entire, they may compose bodies of one and the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things depending on them would be changed. Water and earth, composed of old worn particles, would not be of the same nature and texture now with water and earth composed of entire particles in the beginning. And therefore, that nature may be lasting, the changes of corporeal things are to be placed only in the various separations and new associations and motions of these permanent particles; compound bodies being apt to break, not in the midst of solid particles, but where those particles are laid together, and touch in a few points. It seems farther," he continues, "that these particles have not only a vis inertiæ, accompanied with such passive laws of motion as naturally result from that force, but also that they are moved by certain active principles, such as is that of gravity, and that which causeth fermentation, and the cohesion of bodies. These principles are to be considered not as occult qualities, supposed to result from the specific forms of things, but as general laws of nature, by which the things themselves are formed; their truth appearing to us by phenomena, though their causes are not yet discovered."

Hobbes, Spinoza, &c, maintain that all the beings in the universe are material, and that their differences arise from their different modifications, motions, &c. Thus they conceive that matter extremely subtile, and in a brisk motion, may think, &c. Dr. Berkeley, on the contrary, argues against the existence of matter itself; and endeavours to prove that it is a mere ens rationis, and has no existence out of the mind.

Some late philosophers have advanced a new hypothesis concerning the nature and essential properties of matter. The first of these who suggested, or at least published an account of this hypothesis, was M. Boscovich, in his Theoria Philosophiæ Naturalis. He supposes that matter is not impenetrable, but that it consists of physical points only, endued with powers of attraction and repulsion, taking place at different distances, that is, surrounded with various spheres of attraction and repulsion; in the same manner as solid matter is generally supposed to be. Provided therefore that any body move with a sufficient degree of velocity, or have sufficient momentum to overcome any power of repulsion that it may meet with, it will find no difficulty in making its way through any body whatever. If the velocity of such a body in motion be sufficiently great, Boscovich contends, that the particles of any body through which it passes, will not even be moved out of their place by it. With a degree of velocity something less than this, they will be considerably agitated, and ignition might perhaps be the consequence, though the progress of the body in motion would not be sensibly interrupted; and with a still less momentum it might not pass at all.

Mr. Michell, Dr. Priestley, and some others of our own country, are of the same opinion. See Priestley's History of Discoveries relating to Light, pa. 390.—In conformity to the above hypothesis, our author maintains, that matter is not that inert substance that it has been supposed to be; that powers of attraction or repulsion are necessary to its very being, and that no part of it appears to be impenetrable to other parts. Accordingly, he defines matter to be a substance, possessed of the property of extension, and of powers of attraction or repulsion, which are not distinct from matter, and foreign to it, as it has been generally imagined, but absolutely essential to its very nature and being; so that when bodies are divested of these powers, they become nothing at all. In another place, Dr. Priestley has given a somewhat different account of matter; according to which it is only a number of centres of attraction and repulsion; or more properly of centres, not divisible, to which divine agency is directed; and as sensation and thought are not incompatible with these powers, solidity, or impenetrability, and consequently a vis inertiæ only having been thought repugnant to them, he maintains, that we have no reason to suppose that there are in man two substances absolutely distinct from each other. See Disquisitions on Matter and Spirit.

But Dr. Price, in a correspondence with Dr. Priestley, published under the title of A Free Discussion of the Doctrines of Materialism and Philosophical Necessity, 1778, has suggested a variety of strong objections against this hypothesis of the penetrability of matter, and against the conclusions that are drawn from it. The vis inertia of matter, he says, is the foundation of all that is demonstrated by natural philosophers concerning the laws of the collision of bodies. This, in particular, is the foundation of Newton's philosophy, and especially of his three laws of motion. Solid matter has the power of acting on other matter by impulse; but unsolid matter cannot act at all by impulse; and this is the only way in which it is capable of acting, by any action that is properly its own. If it be said, that one particle of matter can act upon another without contact and impulse, or that matter can, by its own proper agency, attract or repel other matter which is at a distance from it, then a maxim hitherto universally received must be false, that "nothing can act where it is not." Newton, in his letters to Bentley, calls the notion, that matter possesses an innate power of attraction, or that it can act upon matter at a distance, and attract and repel by its own agency, an absurdity into which he thought no one could possibly fall. And in another place he expressly disclaims the notion of innate gravity, and has taken pains to show that he did not take it to be an essential property of bodies: and by pursuing the same kind of reasoning, it must appear, that matter has not the power of attracting and repelling; that this power is the power of some foreign cause, acting upon matter according to stated laws; and consequently that attraction and repulsion, not being actions, much less inherent qualities of matter, as such, it ought not to be defined by them. And if matter has no other property, as Dr. Priestley asserts, than the power of attracting and repelling, it must be a non-entity; because this is a property that cannot belong to it. Besides, all power is the power of something; and yet if matter is nothing but this power, it must be the power of nothing; and the very idea of it is a contradiction. If matter be not solid extension, what can it be more than mere extension?

Further, matter that is not solid, is the same with pore; and therefore it cannot possess what philosophers mean by the momentum or force of bodies, which is always in proportion to the quantity of matter in bodies, void of pore.

MAUNDY THURSDAY, is the Thursday in Passion week; which was called Maunday or Mandate Thursday, from the command which Christ gave his apostles to commemorate him in the Lord's Supper, which he instituted on this day; or from the new commandment which he gave them to love one another, after he had washed their feet as a token of his love to them.

MAUPERTUIS (PETER LOUIS MORCEAU DE), a celebrated French mathematician and philosopher, was born at St. Malo in 1698, and was there privately educated till he attained his 16th year, when he was placed under the celebrated professor of philosophy, M. le Blond, in the college of la Marche, at Paris; he had also M. Guisnée, of the Academy of Sciences, for his instructor in mathematics. For this science he soon discovered a strong inclination, and particularly for geometry. He also practised instrumental music in his early years with great success; but fixed on no profession till he was 20, when he entered into the army; in which he remained about 5 years, during which time he pursued his mathematical studies with great vigour; and it was soon remarked by M. Freret and other academicians, that nothing but mathematics could satisfy his active soul and unbounded thirst for knowledge.

In the year 1723, he was received into the Royal Academy of Sciences, and read his first performance, which was a memoir on the construction and form of musical instruments. During the first years of his admission, he did not wholly confine his attention to mathematics; he dipped into natural philosophy, and discovered great knowledge and dexterity in observations and experiments on animals.

If the custom of travelling into remote countries, like the sages of antiquity, in order to be initiated into the learned mysteries of those times, had still subsisted, no one would have conformed to it with more eagerness than Maupertuis. His first gratification of this passion was to visit the country which had given birth to Newton; and during his residence in London he became as zealous an admirer and follower of that philosopher as any one of his own countrymen. His next excursion was to Basil in Switzerland, where he formed a friendship with the celebrated John Bernoulli and his family, which continued till his death. At his return to Paris, he applied himself to his favourite studies with greater zeal than ever. And how well he fulfilled the duties of an academician, may be seen by running over the Memoirs of the academy from the year 1724 to 1744; where it appears that he was neither idle, nor occupied on objects of small importance. The most sublime questions in the mathematical sciences, received from his hand that elegance, clearness, and precision, so remarkable in all his writings.

In the year 1736, he was sent to the polar circle, to measure a degree of the meridian, in order to ascertain the figure of the earth; in which expedition he was accompanied by Mess. Clairaut, Camus, Monnier, Outhier, and Celsus, the celebrated professor of astronomy at Upsal. This business rendered him so eminent, that on his return he was admitted a member of almost every academy in Europe; though it has been since found that their deductions have been considerably erroneous.

In the year 1740, Maupertuis had an invitation from the king of Prussia to go to Berlin; which was too flattering to be refused. His rank among men of letters had not wholly effaced his love for his first profession, that of arms. He followed the king to the field, but at the battle of Molwitz was deprived of the pleasure of being present, when victory declared in favour of his royal patron, by a singular kind of adventure. His horse, during the heat of the action, running away with him, he fell into the hands of the enemy; and was at first but roughly treated by the Austrian hussars, to whom he could not make himself know for want of language; but being carried prisoner to Vienna, he received such honours from the emperor as neve were effaced from his memory. Maupertuis lamented ver much the loss of a watch of Mr. Graham's, the celebrate English artist, which they had taken from him; but the emperor, who happened to have another by the same artist enriched with diamonds, presented it to him, saying, "the hussars meant only to jest with you, they have sent m your watch, and I return it to you."

He went soon after to Berlin; but as the reform of th academy which the king of Prussia then meditated was no yet matured, he repaired to Paris, where his affairs calle him, and he was there chosen, in 1742, director of th Academy of Sciences. In 1743 he was received into th French Academy; which was the first instance of the sam person being a member of both the academies at Paris a the same time. Maupertuis again assumed the soldier a the siege of Fribourg, and was pitched upon by Marsh Coigny and the count d'Argenson to carry the news to th French king of the surrender of that citadel.

Maupertuis returned to Berlin in the year 1744, whe a marriage was negotiated and brought about, by the goo offices of the queen-mother, between our author ar Mademoiselle de Borck, a lady of great beauty and meri and nearly related to M. de Borck, at that time minist of state. This determined him to settle at Berlin, as l was extremely attached to his new spouse, and regarde this alliance as the most fortunate circumstance of his lit

In the year 1746, Maupertuis was declared, by the kin of Prussia, president of the Royal Academy of Sciences Berlin, and soon after by the same prince was honoure with the Order of Merit. However, all these accumulat honours and advantages, so far from lessening his ardo for the sciences, seemed to furnish new allurements to l bour and application. Not a day passed but he produc some new project or essay for the advancement of knowledge. Nor did he confine himself to mathematical studies only: metaphysics, chemistry, botany, polite literature, all shared his attention, and contributed to his fame. At the same time he had, it seems, a strange inquietude of spirit, and dark melancholy humour, which rendered him miserable amid honours and pleasures. Such a temperament did not promise a pacific life, and he was in fact engaged in several quarrels. One of these was with Koenig, the professor of philosophy at Franeker, and another more terrible with Voltaire. Maupertuis had inserted in the volume of Memoirs of the Academy of Berlin for 1746, a discourse on the laws of motion; which Koenig was not content with attacking, but attributed to Leibnitz. Maupertuis, stung with the imputation of plagiarism, engaged the academy of Berlin to call upon him for his proof, which Koenig failing to produce, his name was struck out of the academy, of which he was a member. Several pamphlets were the consequence of this measure; and Voltaire, for some reason or other, engaged in the quarrel against Maupertuis. We say, for some reason or other; because Maupertuis and Voltaire were apparently on the most amicable terms; and the latter respected the former as his master in the mathematics. Voltaire on this occasion, however, exerted all his wit and satire against him; and on the whole was so much transported beyond what was thought right, that he found it expedient in 1753 to quit the court of Prussia.

Our philosopher's constitution had long been considerably impaired by the great fatigues of various kinds in which his active mind had involved him; though to the amazing hardships he had undergone, in his northern expedition, most of his bodily sufferings may be traced. The intense sharpness of the air could only be supported by means of strong liquors, which helped but to lacerate his lungs, and bring on a spitting of blood, which began at least 12 years before his death. Yet still his mind seemed to enjoy the greatest vigour; for the best of his writings were produced, and most sublime ideas developed, during the time of his confinement by sickness, when he was unable to occupy his presidential chair at the academy. He took several journeys to St. Malo, during the last years of his life, for the recovery of his health: and though he always received benefit by breathing his native air, yet still, on his return to Berlin, his disorder likewise returned with greater violence. His last journey into France was undertaken in the year 1757; when he was obliged, soon after his arrival there, to quit his favourite retreat at St. Malo, on account of the danger and confusion which that town was thrown into by the arrival of the English in its neighbourhood. From thence he went to Bourdeaux, hoping there to meet with a neutral ship to carry him to Hamburgh, in his way back to Berlin; but being disappointed in that hope, he went to Toulouse, where he remained seven months. He had then thoughts of going to Italy, in hopes a milder climate would restore him to health; but finding himself grow worse, he rather inclined towards Germany, and went to Neufchatel, where for three months he enjoyed the conversation of lord Marischal, with whom he had formerly been much connected. At length he arrived at Basil, October 16, 1758, where he was received by his friend Bernoulli and his family with the utmost tenderness and affection. He at first found himself much better here than he had been at Neufchatel: but this amendment was of short duration; for as the winter approached, his disorder returned, accompanied by new and more alarming symptoms. He languished here many months, during which he was attended by M. de la Condamine; and died in 1759, at 61 years of age.

The works which he published were collected into 4 volumes 8vo, published at Lyons in 1756, where also a new and elegant edition was printed in 1768. These contain the following works:—1. Essay on Cosmology.—2. Discourse on the different Figures of the Stars.—3. Essay on Moral Philosophy.—4. Philosophical Reflections on the Origin of Languages, and the Signification of Words.—5. Animal Physics, concerning Generation &c.—6. System of Nature, or the Formation of Bodies.—7. Letters on various Subjects.—8. On the Progress of the Sciences.—9. Elements of Geography.—10. Account of the Expedition to the Polar Circle, for determining the Figure of the Earth; or the Measure of the Earth at the Polar Circle.—11. Account of a Journey into the Heart of Lapland, to search for an Ancient Monument.—12. On the Comet of 1742.—13. Various Academical Discourses pronounced in the French and Prusian Academies.—14. Dissertation on Languages.—15. Agreement of the Different Laws of Nature, which have hitherto appeared incompatible.—16. On the Laws of Motion.—17. On the Laws of Rest.—18. Nautical Astronomy.—19. On the Parallax of the Moon.—20. Operations for determining the Figure of the Earth, and the Variations of Gravity.—21. Measure of a Degree of the Meridian at the Polar Circle.

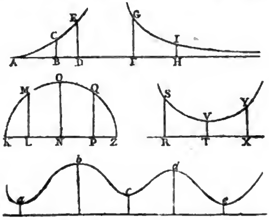
Besides these works, Maupertuis was author of a great number of interesting papers, particularly those printed in the Memoirs of the Paris and Berlin Academies, far too numerous here to mention; viz, in the Memoirs of the Academy at Paris, from the year 1724, to 1749; and in those of the Academy of Berlin, from the year 1746, to 1756.

MAUROLICO (Francis), was born at Messina in 1494, and became abbot of St. Maria del Porto in Sicily, and taught mathematics with reputation in his native country, having possessed the happy art of rendering the most abstract questions plain, by his clearness of expression; and he applied particularly to the summation of several series, such as those of the natural numbers, triangular numbers, &c. He died in 1575.—His works chiefly are, 1. An edition of the Spherics of Theodosius.—2. Emendatio et Restitutio Conicorum Apollonii Pergæi.—3. Archimedis Monumenta omnia.—4. Euclidis Phenomena, &c. And he introduced the use of the secants into trigonometry.

MAXIMUM, denotes the greatest state or quantity attainable in any given case, or the greatest value of a variable quantity. By which it stands opposed to Minimum, which is the least possible quantity in any case. As in the algebraical expression $a^2 - bx$, where a and b are constant or invariable quantities, and x a variable one. Now it is evident that the value of this remainder or difference, $a^2 - bx$, will increase as the term bx, or x, decreases; and therefore that remainder will be the greatest when x is the smallest; that is, $a^2 - bx$ is a maximum, when x is the least, or nothing at all. Again, the expression or difference $a^2 - \frac{b}{x}$, evidently increases as the fraction $\frac{b}{x}$ diminishes; and this diminishes as x increases; therefore the given expression will be the greatest, or a maximum, when x is the greatest, or infinite.

Also, if along the diameter KZ (*the 3d fig. below*) of a circle, a perpendicular ordinate LM be conceived to move, from K towards Z; it is evident that, from K it increases continually till it arrive at the centre, in the position NO, where it is at the greatest state; and from thence it continually decreases again, as it moves along from N to Z, and quite vanishes at the point Z. So that the maximum state of the ordinate is NO, equal to the radius of the circle.

Methodus de MAXIMIS *et* MINIMIS, a method of finding the greatest or least state or value of a variable quantity.



Some quantities continually increase, and therefore have no maximum but what is infinite; as the ordinates BC, DE of the parabola ACE: Some continually decrease, and have therefore their least or minimum state in nothing; as the ordinates FG, HI, to the asymptotes of the hyperbola. Others increase to a certain magnitude, which is their maximum, and then decrease again; as the ordinates LM &c of the circle. And others again decrease to a certain magnitude TV, which is their minimum, and then increase again; as the ordinates of the curve SVY. While others admit of several maxima and minima; as the ordinates of the curve *abcde*, where at *b* and *d* they are maxima, and at *a*,*c*,*e*, minima. And thus the maxima and minima of all other variable quantities may be conceived; expressing those quantities by the ordinates of some curves.

The first ideas of maxima and minima are found in the Elements of Euclid, or flow immediately from them: thus, it appears, by the 5th prop. of book 2, that the greatest rectangle that can be made of the two parts of a given line, any how divided, is when the line is divided equally in the middle; prop. 7, book 3, shows that the greatest line that can be drawn from a given point within a circle, to its circumference, is that which passes through the centre; and that the least line that can be so drawn, is the continuation of the same to the other side of the circle: prop. 8, ib. shows the same for lines drawn from a point without the circle: and thus many instances of a similar nature might be pointed out in the Elements.—Other writers on the maxima and minima, are, Apollonius, in the whole 5th book of his Conic Sections; and in the preface or dedication of that book, he says that others had then also treated the subject, though in a slighter manner.—Archimedes; as in prop. 9 of his treatise on the Sphere and Cylinder, where he demonstrates that, of all spherical segments under equal superficies, the hemisphere is the greatest.—Serenus, in his 2d book, or that on the Conic Sections.—Pappus, in many parts of his Mathematical Collections; as in lib. 3, prop. 28 &c, lib. 6, prop. 31 &c, where he treats of some curious cases of variable geometrical quantities, showing how some increase and decrease both ways to infinity; while others proceed only one way, by increase or decrease, to infinity, and the other way to a certain magnitude; and others again both ways to a certain magnitude, giving a maximum and minimum; also lib. 7, prop. 13, 14, 165, 166, &c. And all these are the geometrical maxima and minima of the ancients; to which may be added some others of the same kind, viz Viviani De Maximis et Minimis Geometrica Divinatio in quintum Conicorum Apollonii Pergæi, in fol. at Flor. 1659; also an ingenious little tract in Simpson's Geometry, on the maxima and minima of Geometrical Quantities. See also vol. 3 of my Course of Mathematics.

But the subject of maxima and minima is treated in a more general way by the modern analysis; the first among which perhaps may be placed that of Fermat. This, and other methods, are best referred to, and explained by the ordinates of curves: for when the ordinate of a curve increases to a certain magnitude, where it is greatest, and afterwards decreases again, it is evident that two ordinates on the contrary sides of the greatest ordinate may be equal to each other; and when the ordinates decrease to a certain point, where they are at the least, and afterwards increase again; there may also be two equal ordinates, one on each side of the least ordinate. Hence then an equal ordinate corresponds to two different abscisses, or for every value of an ordinate there are two values of abscisses. Now as the difference between the two abscisses is conceived to become less and less, it is evident that the two equal ordinates, corresponding to them, approach nearer and nearer together; and when the differences of the abscisses are infinitely small, or nothing, then the equal ordinates unite in one, which is either the maximum or minimum. The method hence derived then, is this: Find two values of an ordinate, expressed in terms of the abscisses: put those two values equal to each other, canceling the parts that are common to both, and dividing all the remaining terms by the difference between the abscisses, which will be a common factor in them: next, supposing the abscisses to become equal, that the equal ordinates may concur in the maximum or minimum, that difference will vanish, as well as all the terms of the equation that include it; and therefore, striking those terms out of the equation, the remaining terms will give the value of the absciss corresponding to the maximum or minimum.

For example, Suppose it were required to find the greatest ordinate in a circle KMQ. Put the diameter KZ $= a$, the absciss KL $= x$, the ordinate LM $= y$; hence the other part of the diameter is LZ $= a - x$, and consequently, by the nature of the circle KL × LZ being equal LM^2, $x \times (a - x)$ or $ax - x^2 = y^2$. Again, put another absciss KP $= x + d$, where d is the difference LP, the ordinate PQ, being equal to LM or y; here then again KP × PZ $=$ PQ^2, or $(x + d) \times (a - x - d) = ax - x^2 - 2dx + ad - d^2 = y^2$: put now these two values of y^2 equal to each other, so shall $ax - x^2 = ax - x^2 - 2dx + ad - d^2$; cancel the common terms ax and x^2, then $0 = -2dx + ad - d^2$, or $2dx + d^2 = ad$; divide all by d, so shall $2x + d = a$, a general equation derived from the equality of the two ordinates. Now, bringing the two equal ordinates together, or making the two abscisses equal, their difference d vanishes, and the last equation becomes barely $2x = a$, or $x = \frac{1}{2}a$, = KN, the value of the absciss KN when the ordinate NO is a maximum, viz, the greatest ordinate bisects the diameter. And the operation and conclusion it is evident will be the same, to divide a given line into two parts, so that their rectangle shall be the greatest possible.

For a second example, let it be required to divide the given line AB into two such parts, that the one part drawn into the square of the other may be the greatest possible.

Putting the given line AB = a, and one part AC = x; then the other part CB will be $a - x$, and therefore $x^2 \times (a - x) = ax^2 - x^3$ is the product of one part by the square of the other. Again, let one part be AD = $x + d$, then the other part is $a - x - d$, and $(x + a)^2 \times (a - x - d) = ax^2 - x^3 - 3dx^2 + (2ad - 3d^2) . x + ad^2 - d^3$. Then, putting these two products equal to each other, cancelling the common terms $ax^2 - x^3$, and dividing the remainder by d, there results $0 = -3x^2 + (2a - 3d) . x + ad - d^2$; hence, canceling all the terms that contain d, there remains $0 = -3x^2 + 2ax$, or $3x = 2a$, and $x = \frac{2}{3}a$; that is, the given line must be divided into two parts in the ratio of 3 to 2. See Fermat's Opera Varia, pa. 63, and his Letters to Mersenne.

The next method was that of John Hudde, given by Schooten among the additions to Descartes's Geometry, near the end of the 1st vol. of his edition. This method is also drawn from the property of an equation having two equal roots. He there demonstrates that, having ranged the terms of an equation, that has two roots equal, according to the order of the exponents of the unknown quantity, taking all the terms over to one side, and so making them equal to nothing on the other side; if then the terms in that order be multiplied by the terms of any arithmetical progression, the resulting equation will still have one of its roots equal to one of the two equal roots of the former equation. Now since, by what has been said of the foregoing method, when the ordinate of a curve, admitting of a maximum or minimum, is expressed in terms of the abscissa, that abscissa, or the value of x, will be two-fold, because there are two ordinates of the same value; that is, the equation has at least two unequal roots or values of x: but when the ordinate becomes a maximum or minimum, the two abscisses unite in one, and the two roots, or values of x, are equal; therefore, from the above-said property, the terms of this equation for the maximum or minimum being multiplied by the terms of any arithmetical progression, the root of the resulting equation will be one of the said equal roots, or the value of the absciss x when the ordinate is a maximum.

Though the terms of any arithmetic progression may be used for this purpose, some are more convenient than others; and Mr. Hudde directs to make use of that progression which is formed by the exponents of x, viz, to multiply each term by the exponent of its power, and putting all the resulting products equal to nothing; which, it is evident, is exactly the same process as taking the fluxions of all the terms, and putting them equal to nothing; being the common process now used for the same purpose.

Thus, in the former of the two foregoing examples, where $ax - x^2$, or y^2, is to be a maximum;
mult. by 1 2
gives $ax - 2x^2 = 0$; hence $2x = a$, and $x = \frac{1}{2}a$, as before.

And in the 2d example, where $ax^2 - x^3$, is to be a maximum; mult. by - - 2 3
gives - - - - $2ax^2 - 3x^3 = 0$;
hence $2a - 3x = 0$, or $3x = 2a$, and $x = \frac{2}{3}a$, as before.

The next general method, and which is now usually practised, is that of Newton, or the method of Fluxions, which is founded on a principle different from that of the two former methods of Fermat and Hudde. These are derived from the idea of the two equal ordinates of a curve uniting into one, at the place of the maximum and minimum; but Newton's from the principle, that the fluxion or increment of an ordinate is nothing, at the point of the maximum or minimum; a circumstance which immediately follows from the nature of that doctrine: for, since a quantity ceases to increase at the maximum, and to decrease at the minimum, at those points it neither increases nor decreases; and since the fluxion of a quantity is proportional to its increase or decrease, therefore the fluxion is nothing at the maximum or minimum. Hence this rule: Take the fluxion of the algebraical expression denoting the maximum or minimum, and put it equal to nothing; and that equation will determine the value of the unknown letter or quantity in question.—So, in the first of the two foregoing examples, where it is required to determine x when $ax - x^2$ is a maximum: the fluxion of this is $a\dot{x} - 2x\dot{x} = 0$; which divided by $\dot{x}$, gives $a - 2x = 0$, or $a = 2x$, and $x = \frac{1}{2}a$. Also, in the 2d example, where $ax^2 - x^3$ is to be a maximum: the fluxion is $2ax\dot{x} - 3x^2\dot{x} = 0$; hence $2a - 3x = 0$, or $2a = 3x$, and $x = \frac{2}{3}a$.

When a quantity becomes a maximum or minimum, and is expressed by two or more affirmative and negative terms, in which only one variable letter is contained; it is evident that the fluxion of the affirmative terms will be equal to the fluxion of the negative ones; since their difference is equal to nothing.

And when, in the expression for the fluxion of a maximum or minimum, there are two or more fluxionary letters, each contained in both affirmative and negative terms; the sum of the terms containing the fluxion of each letter, will be equal to nothing: For, in order that any expression be a maximum or minimum, which contains two or more variable quantities, it must produce a maximum or minimum, if but one of those quantities be supposed variable. So if $ax - 2xy + by$ denote a minimum; its fluxion is $a\dot{x} - 2y\dot{x} - 2x\dot{y} + b\dot{y}$; hence $a\dot{x} - 2y\dot{x} = 0$, and $b\dot{y} - 2x\dot{y} = 0$; from the former of these $y = \frac{1}{2}a$, and from the latter $x = \frac{1}{2}b$. Or, in such a case, take the fluxion of the whole expression, supposing only one quantity variable; then take the fluxion again, supposing another quantity only variable: and so on, for all the several variable quantities; which will give the same number of equations for determining those quantities. So, in the above example, $ax - 2xy + by$, the fluxion is $a\dot{x} - 2y\dot{x} = 0$, supposing only x variable; which gives $y = \frac{1}{2}a$: and the fluxion is $-2x\dot{y} + b\dot{y} = 0$, when y only is variable; which gives $x = \frac{1}{2}b$; the same as before.

Farther, when any quantity is a maximum or minimum, all the powers or roots of it will be so too; as will also be the result, when it is increased or decreased, or multiplied, or divided by a given or constant quantity; and the logarithm of the same will be also a maximum or minimum.

To find whether a proposed algebraic quantity admits of a maximum or minimum.—Every algebraic expression does not admit of a maximum or minimum, properly so called; for it may either increase continually to infinity, or decrease continually to nothing; in both which cases there is neither a proper maximum nor minimum: for the true maximum is that value to which an expression increases, and after which it decreases again; and the minimum is that value to which the expression decreases, and after that it increases again. Therefore when the expression admits of a maximum, its fluxion is positive before that point, and negative after it; but when it admits of a minimum, its fluxion is negative before, and positive after it. Hence, take the fluxion of the expression immediately before the fluxion is equal to nothing, and a little after it; if the first fluxion be positive, and the last negative, the middle state is a maximum; but if the first fluxion be negative, and the last positive, the middle state is a minimum. Thus, for example, see Maclaurin's Fluxions, book 1, chap. 9, and book 2, chap. 5, art. 859.

We shall add here a few problems, as a farther illustration of this method.

Prob. 1. To divide a given number a into two parts, x, and y, so that $x^m y^n$ may be a maximum.

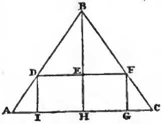
Since $x + y = a$, and $x^m y^n =$ max. the fluxion of each $= 0$, the former because it is constant, and the latter because it is a maximum; therefore $\dot{x} + \dot{y} = 0$ and $my^n x^{m-1}\dot{x} + nx^m y^{n-1}\dot{y} = 0$; hence $\dot{x} = -\dot{y}$, and $\dot{x} = -\frac{nx^m y^{n-1}\dot{y}}{my^n x^{m-1}} = -\frac{nx\dot{y}}{my}$; therefore $-\dot{y} = -\frac{nx\dot{y}}{my}$, or $my = nx$, that is $m : n :: x : y$. And since $y = \frac{nx}{m}$; therefore $x + \frac{nx}{m} = a$, and consequently $x = \frac{ma}{m+n}$, and $y = \frac{na}{m+n}$.

If $m = n$, the two parts are equal.

Prob. 2. To inscribe the greatest parallelogram in a given triangle.

Let ABC, Fig. 1, be the given triangle, and DFGI the required parallelogram; draw BH perpendicular to AC; and put AC $= a$, BH $= b$, BE $= x$; then EH $= b - x$; and by similar triangles $b : a :: x : \frac{ax}{b} =$ DF; hence the area DFGI $= \frac{ax}{b} \times (b - x) =$ max. or $bx - x^2 =$ max. Therefore, taking the fluxion, we have, $b\dot{x} - 2x\dot{x} = 0$, or $x = \frac{1}{2}b$; and hence EH $= \frac{1}{2}$BH.

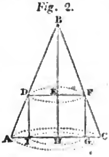
Fig. 1.



Prob. 3. To inscribe the greatest cylinder in a given cone.

Let ABC, Fig. 2, represent the given cone, and DFGI the cylinder required. Put $p = \cdot78539$ &c; then the same notation remaining, as in the foregoing problem, we have by similar triangles, $b : a :: x : \frac{ax}{b} =$ DF; therefore the area of the end of the cylinder $= \frac{pa^2x^2}{b^2}$; and hence, by the question, $\frac{pa^2x^2}{b^2} \times (b - x) =$ a max. or $x^2 \times (b - x) = bx^2 - x^3 =$ a max. And this being thrown into fluxions, we have $2bx\dot{x} - 3x^2\dot{x} = 0$, or $x = \frac{2}{3}b$; therefore EH $= \frac{1}{3}$BH, when the cylinder is the greatest possible.

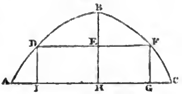
Fig. 2.



Prob. 4. To inscribe the greatest possible parallelogram in a given parabola.

Let ABC, Fig. 3, represent the given parabola, and DFGI the required parallelogram. Also put BH $= a$, parameter $= p$, and BE $= x$; then by the property of the parabola, DE$^2 = px$; therefore DE $= \sqrt{px}$, and DF $= 2\sqrt{px}$; hence the area of the parallelogram DFGI $= 2\sqrt{px} \times (a - x)$ a max. or $ax^{\frac{1}{2}} - x^{\frac{3}{2}} =$ a max.; and this in fluxions gives $\frac{1}{2}ax^{-\frac{1}{2}}\dot{x} - \frac{3}{2}x^{\frac{1}{2}}\dot{x} = 0$, or $\frac{a}{x^{\frac{1}{2}}} = 3x^{\frac{1}{2}}$ or $a = 3x$, consequently $x = \frac{1}{3}a$; that is EH $= \frac{2}{3}$ BH, when the inscribed parallelogram is a maximum.

Fig. 3.



Prob. 5. To determine the dimensions of a cylindric vessel open at top, that shall contain a given quantity o liquor, under the least possible superficies.

Let the altitude be represented by x, and the diamete by y, also put $\cdot78539$ &c $= p$, consequently $3\cdot1416 = 4p$ and the content $= a$; then $4pxy$ will be the cylindric surface, and py^2 the area of the bottom. Hence these tw equations $py^2x = a$, and $4pxy + py^2 =$ a minimum from the first $x = \frac{a}{py^2}$, which being substituted for x i the second, gives $\frac{4a}{y} + py^2 =$ a minimum; and this i fluxions, gives $\frac{-4a\dot{y}}{y^2} + 2py\dot{y} = 0$, or $2py = \frac{4a}{y^2}$; henc $y^3 = \frac{2a}{p}$, and $y = \sqrt[3]{\frac{2a}{p}}$ the diameter; also since $x = \frac{a}{py^2}$ or $x^3 = \frac{a^3}{p^3y^6} = \frac{a^3}{p^3} \times \frac{p^2}{4a^2} = \frac{a}{4p} = \frac{2a}{8p}$; therefore $x = \frac{1}{2}\sqrt[3]{\frac{2a}{p}}$: that is, the diameter is double the altitud when the surface is a minimum.

Prob. 6. Of all right-angled triangles having the sar hypothenuse, to determine the dimensions of that who area is a maximum.

Let the hypothenuse be represented by a, and the le by x and y. Then we have these two equations,

$$x^2 + y^2 = a^2, \text{ and } \tfrac{1}{2}xy = \text{max.}$$

The fluxion of each of these is equal to 0, the first b cause it is constant, and the second because it is a max mum; we have therefore $2x\dot{x} + 2y\dot{y} = 0$, and $\frac{1}{2}x\dot{y} + \frac{1}{2}y\dot{x} = 0$; from the fi $\dot{x} = \frac{-y\dot{y}}{x}$ and from the second $\dot{x} = \frac{-x\dot{y}}{y}$, therefore $\frac{y\dot{y}}{x} = \frac{x\dot{y}}{y}$; hence $x = y$, that is, the area is a maximu when the legs are equal.

For various examples of this kind, see Simpson's, Ma laurin's, Emerson's, and Vince's Fluxions.

MAXIMUM *Effect of Machines*. See MECHANICS.

MAY, *Maius*, the fifth month in the year, reckoni from our first, or January; but the third, counting t year to begin with March, as the Romans did ancientl It was called Maius by Romulus, in respect to the ser tors and nobles of his city, who were named Majores; as the following month was called Junius, in honour of the youth of Rome, in honorem juniorum, who served him in the war. Though some say it has been thus called from Maia, the mother of Mercury, to whom they offered sacrifice on the first day of this month: and Papias derives the name from Madius, eo quod tunc terra madeat.—In this month the sun enters the sign Gemini, and the plants of our hemisphere begin mostly to flower.

MAYER (TOBIAS), one of the greatest astronomers and mechanists of the 18th century, was born at Maspach, in the duchy of Wirtemberg, 1723. He taught himself mathematics, and at 14 years of age designed machines and instruments with the greatest dexterity and exactness. These pursuits, however, did not hinder him from cultivating the belles lettres; for he acquired the Latin tongue, and wrote it with elegance. In 1750, the university of Gottingen chose him for their mathematical professor; and every year of his short life was thenceforward marked with some considerable discoveries in geometry and astronomy. He published several works on these subjects, which are all accounted excellent of their kind; and some papers are inserted in the second volume of the Memoirs of the University of Gottingen. He was very accurate and indefatigable in his astronomical observations; indeed his labours seem to have very early exhausted him; for he died worn out in 1762, at no more than 39 years of age.

His Table of Refractions, deduced from his own astronomical observations, accurately agrees with that of Doctor Bradley; and his Theory of the Moon, and Astronomical Tables and Precepts, were so well esteemed, that they were rewarded by the English Board of Longitude, with the premium of 3000 pounds, which sum was paid to his widow after his death. These tables and precepts were published by the Board of Longitude in 1770.

MEAN, a middle state between two extremes: as a mean motion, mean distance, arithmetical mean, geometrical mean, &c.

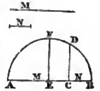
Arithmetical MEAN, is half the sum of the extremes. So, 4 is an arithmetical mean between 2 and 6, or between 3 and 5, or between 1 and 7; also an arithmetical mean between a and b is $\frac{a+b}{2}$ or $\frac{1}{2}a + \frac{1}{2}b$.

Geometrical MEAN, commonly called a mean proportional, is the square root of the product of the two extremes; so that, to find a mean proportional between two given extremes, multiply these together, and extract the square root of the product. Thus, a mean proportional between 1 and 9, is $\sqrt{(1 \times 9)} = \sqrt{9} = 3$; a mean between 2 and $4\frac{1}{2}$ is $\sqrt{(2 \times 4\frac{1}{2})} = \sqrt{9} = 3$; also the mean between 4 and 6 is $\sqrt{(4 \times 6)} = \sqrt{24}$; and the mean between a and b is $\sqrt{ab}$.

The geometrical mean is always less than the arithmetical mean, between the same two extremes. So the arithmetical mean between 2 and $4\frac{1}{2}$ is $3\frac{1}{4}$, but the geometrical mean is only 3. To prove this generally; let a and b be any two terms, a the greater, and b the less; then, universally, the arithmetical mean $\frac{1}{2}a + \frac{1}{2}b$ shall be greater than the geometrical mean $\sqrt{ab}$, or $a + b$ greater than $2\sqrt{ab}$. For, by

squaring both, they are $a^2 + 2ab + b^2 > 4ab$;
subtr. $4ab$ from each, then $a^2 - 2ab + b^2 > 0$,
that is - - - - $(a - b)^2 > 0$.

To find a Mean Proportional Geometrically, between two given lines M and N. Join the two given lines together at C in one continued line AB; on the diameter AB describe a semicircle, and erect the perpendicular CD; which will be the mean proportional between AC and CB, or M and N. This, it is evident, is always less than the arithmetical mean, AE or EB or EF; except when the two lines are equal; for then the two means are equal also.



To find two Mean Proportionals between two given extremes. Multiply each extreme by the square of the other, viz, the greater extreme by the square of the less, and the less extreme by the square of the greater; then extract the cube root out of each product, and the two roots will be the two mean proportionals sought. That is, $\sqrt[3]{a^2b}$ and $\sqrt[3]{ab^2}$ are the two means between a and b. So, between 2 and 16, the two mean proportionals are 4 and 8; for $\sqrt[3]{(2^2 \times 16)} = \sqrt[3]{64} = 4$, and $\sqrt[3]{(2 \times 16^2)} = \sqrt[3]{512} = 8$.

In a similar manner we proceed for three means, or four means, or five means, &c. From all which it appears that the series of the several numbers of mean proportionals, between a and b, will be as follows: viz,

one mean, $\sqrt{ab}$;
two means, $\sqrt[3]{a^2b}$, $\sqrt[3]{ab^2}$;
three means, $\sqrt[4]{a^3b}$, $\sqrt[4]{a^2b^2}$, $\sqrt[4]{ab^3}$;
four means, $\sqrt[5]{a^4b}$, $\sqrt[5]{a^3b^2}$, $\sqrt[5]{a^2b^3}$, $\sqrt[5]{ab^4}$;
five means, $\sqrt[6]{a^5b}$, $\sqrt[6]{a^4b^2}$, $\sqrt[6]{a^3b^3}$, $\sqrt[6]{a^2b^4}$, $\sqrt[6]{ab^5}$;
&c, &c.

Harmonical MEAN, is double a fourth proportional to the sum of the extremes, and the two extremes themselves a and b: thus, as $a + b : a :: 2b : \frac{2ab}{a+b} = m$ the harmonical mean between a and b. Or it is the reciprocal of the arithmetical mean between the reciprocals of the given extremes; that is, take the reciprocals of the extremes a and b, which will be $\frac{1}{a}$ and $\frac{1}{b}$; then take the arithmetical mean between these reciprocals, or half their sum, which will be $\frac{1}{2a} + \frac{1}{2b}$ or $\frac{a+b}{2ab}$; lastly, the reciprocal of this is $\frac{2ab}{a+b} = m$ the harmonical mean: for, arithmeticals and harmonicals are mutually reciprocals of each other;

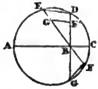
so that if a, m, b, &c be arithmeticals,
then shall $\frac{1}{a}, \frac{1}{m}, \frac{1}{b}$, &c be harmonicals;

or if the former be harmonicals, the latter will be arithmeticals.

For example, to find a harmonical mean between 2 and 6; here $a = 2$, and $b = 6$; therefore $\frac{2ab}{a+b} = \frac{2 \times 2 \times 6}{2 + 6} = \frac{24}{8} = 3 = m$ the harmonical mean sought between 2 and 6.

It is remarkable that the three means, viz, the arithmetical, the geometrical, and the harmonical, between any two quantities, a and b, are in continued geometric progression; for it is evident that $\frac{a+b}{2} : \sqrt{ab} :: \sqrt{ab} : \frac{2ab}{a+b}$.

To place the said three Means in a Circle.—On the sum (AC) of the two means (AB, BC), as a diameter, describe a circle; in which erect BD the given mean, and apply $BE = \frac{1}{2}AC$ the arithm. mean, then produce EB to F, so shall BF be the harmonical mean. For, produce DB to



G, then BG = BD; also join DE and FG, making the triangles BDE, BFG similar: for the opposite angles at B are equal, also the angles E and G are equal, standing on the same arc DF; hence BE : BD :: BG = BD : BF, which is therefore the harmonical mean.

Otherwise; Having drawn BE and BD, the arithm. and geom. means; take BG′ = BD, and draw G′F′ parallel to ED; then is BF′ = BF the harm. mean also. For, by sim. triangles, BE : BD :: BG′ = BD : BF′.

In the 3d book of Pappus's Mathematical Collections, we have a very good tract on all the three kinds of mean proportionals, beginning at the 5th proposition. He observes, that the ancients could not resolve, in a geometrical way, the problem of finding two mean proportionals; and because it is not easy to describe the conic sections in plano, for that purpose, they contrived easy and convenient instruments, by which they obtained good mechanical constructions of that problem; as appears by their writings; as in the Mesolabe of Eratosthenes, of Philo, with the Mechanics and Catapultics of Hero. For these, rightly deeming the problem a solid one, effected the construction only by instruments, and Apollonius Pergæus by means of the conic sections; which others again performed by the loci solidi of Aristæus; also Nicomedes solved it by the conchoid, by means of which likewise he trisected an angle: and Pappus himself gave another solution of the same problem.

Pappus adds definitions of the three foregoing different kinds of means, with many problems and properties concerning them; and, among others, this curious similarity of them, viz, a, m, b, being three continued terms, either arithmeticals, geometricals, or harmonicals; then in the

Arithmeticals, $a : a :: a - m : m - b$;
Geometricals, $a : m :: a - m : m - b$;
Harmonicals, $a : b :: a - m : m - b$.

MEAN-*and-Extreme Proportion*, or *Extreme-and-Mean Proportion*, is when a line, or any quantity, is so divided, that the less part is to the greater, as the greater is to the whole.—This is easily performed geometrically, as is done in Euclid.

But it cannot be done arithmetically in rational numbers: for if a denote a given number, to be divided in extreme-and-mean ratio; then the two parts are $\frac{\sqrt{5}-1}{2}a$ and $\frac{3-\sqrt{5}}{2}a$, which cannot be given in rational numbers, on account of the radical $\sqrt{5}$.

MEAN *Anomaly*, of a planet, is an angle, which is always proportional to the time of the planet's motion from the aphelion or perihelion, or proportional to the area described by the radius vector; that is, as the whole periodic time in one revolution of the planet, is to the time past the aphelion or perihelion, so is 360° to the mean anomaly. See ANOMALY.

MEAN *Axis*, in Optics. See AXIS.

MEAN *Conjunction* or *Opposition*, is when the mean place of the sun is in conjunction, or opposition, with the mean place of the moon in the ecliptic.

MEAN *Diameter*, in Gauging, is a mean between the diameters at the head and bung of a cask.

MEAN *Distance*, of a planet from the sun, is an arithmetical mean between the planet's greatest and least distances; and this is equal to the semitransverse axis of the elliptic orbit in which it moves, or to the right line drawn from the sun or focus to the extremity of the conjugate axis of the same.

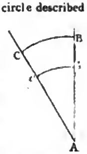
MEAN *Motion*, is that by which a planet is supposed to move equably in its orbit; and it is always proportional to the time.

MEAN *Time*, or Equal Time, is that which is measured by an equable motion, as a clock; as distinguished from apparent time, arising from the unequal motion of the earth or sun.

MEASURE, denotes any quantity, assumed as unity, or one, to which the ratio of other homogeneous or like quantities may be expressed.

Quantities are not always necessarily measured by quantities of the same kind. See vol. 3 of my Course of Mathematics, pa. 87, the note.

MEASURE *of an Angle*, is an arc of a circle described from the angular point as a centre, and intercepted between the legs or sides of the angle: and it is usual to estimate and express the measure of the angle by the number of degrees and parts contained in that arc, of which 360 make up the whole circumference. So, the measure of the angle BAC, is the arc BC to the radius AB, or the arc bc to the radius Ab.



Hence, a right angle is measured by a quadrant, or 90 degrees; and any angle, as BAC, is to a right angle, as the arc BC is to a quadrant, or as the degrees in BC are to 90 degrees.

Common MEASURE. See COMMON *Measure*.

MEASURE *of a Figure*, or Plane Surface, is a square inch, or square foot, or square yard, &c, that is, a square whose side is an inch, or a foot, or a yard, or some other determinate length; and this square is called the *measuring unit*.

MEASURE *of a Line*, is any right line taken at pleasure, and considered as unity; as an inch, or a foot, or a yard, &c.

Line of MEASURES. See LINE *of Measures*.

MEASURE *of a Mass*, or *Quantity of Matter*, is its weight.

MEASURE *of a Number*, is any number that divides it, without leaving a remainder. So, 2 is a measure of 4, of 8, or of any even number; and 3 is a measure of 6, or of 9, or of 12, &c.

MEASURE *of a Ratio*, is its logarithm, in any system of logarithms; or it is the exponent of the power to which the ratio is equal, the exponent of some given ratio being assumed as unity. So, if the logarithm or measure of the ratio of 10 to 1, be assumed equal to 1; then the measure of the ratio of 100 to 1, will be 2, because 100 is $= 10^2$, or because 100 to 1 is in the duplicate ratio of 10 to 1; and the measure of the ratio of 1000 to 1, will be 3, because 1000 is $= 10^3$, or because 1000 to 1 is triplicate of the ratio of 10 to 1.

MEASURE *of a Solid*, is the number of cubic inches, or cubic feet, or cubic yards, &c, that are contained in it.

MEASURE *of a Superficies*, is the number of square inches, or square feet, or square yards, &c, contained in it.

MEASURE *of Velocity*, is the space uniformly passed over by a moving body in a given time.

Universal or *Perpetual* MEASURE, is a kind of measure unalterable by time or place, to which the measures of different ages and nations might be reduced, and by which they may be compared and estimated. Such a measure would be very useful, if it could be attained; since, being used at all times, and in all places, a great deal of confusion and error would be avoided.

Measures of length appear to be the originals for all others, both for surfaces and solids or capacities, as well as for weights. The long measures of all nations seem, from their names, to have been originally taken from some part of the human body; as the foot, the hand, the cubit or elbow, the span, the fathom, &c. But as these measures must differ according to the different sizes of men, standards of some durable substance have been adopted in all civilised countries; which are found however to differ universally from each other, to the great inconvenience of all commerce. In order to remedy this inconvenience, different methods have been proposed for establishing a universal and perpetual standard, unalterable by time or place, to which the measures of all nations might be reduced, and by which they might be occasionally adjusted. But as all material substances are liable to decay and alteration, an invariable standard can be obtained only from some stable principle in nature, such as the action of gravitation, the motions of the heavenly bodies, or the magnitude of the earth, &c; and accordingly several of such methods have been proposed, of which the two following only have been attended with any degree of success; viz, 1. The length of a pendulum that vibrates seconds of mean time; 2. The length of a certain division or arc of the meridian.

The first of these methods is liable to this inconvenience, that the length of a seconds pendulum varies in different latitudes, increasing from the equator to the poles, owing to the spheroidical figure of the earth. The second method is liable to a similar inconvenience; as, from the same cause, the degrees of the meridian must also increase from the equator to the poles. Sir I. Newton calculated that the equatorial diameter of the earth is to the polar diameter, as 230 to 229; and therefore that on different parts of the earth's surface the weight of the same body is different, according as it is more or less distant from the centre of the earth; so that the length of a pendulum, vibrating any equal portions of time, must increase from the equator to the poles; and the degrees of the meridian must also increase on account of the curvature of the oblate spheroid.

Several measurements have been made in different latitudes, both of the lengths of the pendulum vibrating seconds, and of the degrees of the meridian; and they have been found nearly to agree with the above theory. Hence it appears, that a universal standard cannot be obtained from any of these methods, unless all nations were to agree that the trial or measurement should be made in some particular latitude;—an agreement that is never likely to take place. Such methods however may be usefully applied, to preserve the standards already established sufficiently correct for all practical purposes.

Huygens, in his Horol. Oscil. proposes, for this purpose, the length of a pendulum that should vibrate seconds, measured from the point of suspension to the point of oscillation: the 3d part of such a pendulum to be called horary foot, and to serve as a standard to which the measure of all other feet might be referred. But this measure, in order to its being universal, supposes that the action of gravity is the same on every part of the earth's surface, which is contrary to fact: for which reason it would really serve only for places under the same parallel of latitude: so that, if all latitudes were to have its foot equal to the 3d part of the pendulum vibrating seconds there, every different latitude would still have a different length of foot. And besides, the difficulty of measuring exactly the distance between the centres of motion and oscillation are such, that hardly any two measures would make it the same quantity.

Since that time, various other expedients have been proposed for establishing a universal measure. In 1779, a method was proposed to the Society of Arts, &c, by a Mr. Hatton, in consequence of a premium, which had been 4 years advertised by that institution, of a gold medal, or 100 guineas, 'for obtaining invariable standards for weights and measures, communicable at all times and to all nations.' Mr. Hatton's plan consisted in the application of a moveable point of suspension to one and the same pendulum, in order to produce the full and absolute effect of two pendulums, the difference of whose lengths was the intended measure. Mr. Whitehurst much improved on this idea, by very curious and accurate machinery, in his tract published 1787, entitled An Attempt towards obtaining invariable Measures of Length, Capacity, and Weight, from the Mensuration of Time, &c. Mr. Whitehurst's plan is, to obtain a measure of the greatest length that conveniency will permit, from two pendulums whose vibrations are in the ratio of 2 to 1, and whose lengths coincide with the English standard in whole numbers. The numbers he has chosen show great ingenuity. On a supposition that the length of a seconds pendulum, in the latitude of London, is 39·2 inches, the length of one vibrating 42 times in a minute, must be 80 inches; and of another vibrating 84 times in a minute, must be 20 inches; their difference, 60 inches or 5 feet, is his standard measure. By his experiments, however, the difference in the lengths of the two pendulums was found to be 59·892 inches, instead of 60, owing to the error in the assumed length of the seconds pendulum, 39·2 inches being greater than the truth. Mr. Whitehurst has however so far accomplished his design, as to show how an invariable standard may, at all times, be found for the same latitude. He has also ascertained a fact, as accurately as human powers seem capable of ascertaining it, of great consequence in natural philosophy: which is, that the difference between the lengths of the rods of two pendulums whose vibrations are known, is a datum from which may be derived the true length of pendulums, the spaces through which heavy bodies fall in a given time, with many other particulars relative to the doctrine of gravitation, the figure of the earth, &c, &c. The result deduced from this experiment is, that the length of a seconds pendulum, vibrating in a circular arc of 3° 20′, is 39·119 inches very nearly; but vibrating in the arc of a cycloid it would be 39·136 inches; and hence, heavy bodies will fall, in the first second of their descent, 16·094 feet, or 16 feet $1\frac{1}{8}$ inch, very nearly.

The other method, of deriving a standard from an arc of the meridian, has been lately executed in France; and it is said to possess the advantage over the pendulum method, of being on a larger scale; as any error in this operation must be dimininished by subdivision; whereas, an error in the small standard must be increased by multiplication. But this method is objected to, on account of the inequality in the earth's surface; for it has been found that the degrees of the meridian vary in different longitudes, even in the same latitude.

The mathematicians who adopted this plan, objected to the pendulum method, as depending on two different elements, viz, gravitation and time. But gravitation is uniform in the same latitude; and time is universally so, as depending on the regularity of the earth's diurnal rotation on its axis, which has never been found to vary, notwithstanding the inequality in its periodical revolution.—Thus it appears that superior accuracy cannot be ascribed to the meridian method; and as the chief use of an original standard from nature, is to restore lost measures; if two methods are equally correct, that which can be performed with the greater convenience, ought to be preferred; and in this view the pendulum must have a decided preference, as affording the readier means of recurring to the original.

Be that however as it may, the fundamental standard adopted in France, for the new system of weights and measures, is a quadrant of the meridian. This quadrant is divided into ten millions of equal parts; and one of these parts or divisions is called a Metre, which is adopted as the unit of length; and from which, by decimal multiplication and division, all other measures are derived. The length of the quadrant has been computed, by measuring an arc of the meridian, between the parallels of Dunkirk and Barcelona; and its length has been thus found equal to 5130740 French toises. This quantity, divided by ten millions, gives 443·296 lines = 36·9413 French inches = 39·3702 English inches, for the length of the metre.

In order to express certain decimal proportions, the following vocabulary has been adopted. The word Deca prefixed, means 10 times; Hecto, 100 times; Kilo, 1000 times; and Myria 10,000 times. On the other hand, the word Deci expresses the 10th part; Centi, the 100th part; and Milli, the 1000th part: thus a decametre, means 10 metres; a decimetre, the 10th part of a metre; a hectometre, 100 metres; a centimetre, the 100th part of a metre; and so of the rest.

The metre then being the element of long measures; the Are, which is a square decametre, is the element of superficial measures; the Stere, which is a cubic metre, is the element of solid measures; the Litre, which is a cubic decimetre, is the element of liquid measures, and of all other measures of capacity; and lastly, the Gramme, which is the weight of a cubic centimetre of distilled water, is the element for all weights.

A third standard has been proposed, viz, the space that a heavy body would freely fall through in a second of time, which in the latitude of London has been found to be nearly $16\frac{1}{12}$ feet. But this, like the above standards, must vary in different latitudes; and the operation is besides extremely difficult to be performed with accuracy.

The ancients mostly adjusted their standards by the dimensions of some durable buildings. In Egypt, the base of one of the pyramids was used; and it is stated by Paucton, that a degree of the meridian was also measured there at a very early period, by which the Greeks and Romans adjusted their standards.

Measure, in a legal, commercial, and popular sense, denotes a certain quantity or proportion of any thing, bought, sold, valued, or the like. The regulation of weights and measures ought to be universally the same throughout the nation, and indeed all nations; and they should therefore be reduced to some fixed rule or standard. Measures are various, according to the various kinds or dimensions of the things measured. Hence arise

Lineal or *Longitudinal* Measures, for lines or lengths:

Square Measures, for areas or superficies: and

Solid or *Cubic* Measures, for the solid contents and capacities of bodies.

The standards of English weights and measures, lik those of all other countries, are uncertain in their origin That of long measure is said to have been fixed in the year 1101, by Henry the 1st, who ordained that the ancient ulna or arm, which answers to the modern yard (the Saxon gyrd or girth), should be adjusted to the length o his arm. This standard is subdivided into feet, inches and barley-corns; and multiplied into poles, furlongs miles, &c. The standards of English weights appear t have been originally from grains of wheat; 32 of whicl were directed, by the Compositio Mensurarum, to make pennyweight, and 20 pennyweights an ounce.

The standards, both of English weights and measure are chiefly kept in the Exchequer at Westminster, fro which copies are taken, and committed to the care of magistrates and other officers, in different parts of the kingdom, who are empowered to examine the weights an measures of their respective districts, and to condem such as are found erroneous. From the Excheque standards are obtained for public offices, and also for individuals, with indentures or licences for sizing, adjusting and vending weights and measures. The principal offic of this kind is at Guildhall, London, where several ancient standards are kept, and occasionally compared wi those of the Exchequer. Here the avoirdupois weight which are cast by the Founders' Company, for the use the city and for other purchasers, are sized and sealed and measures of capacity are likewise adjusted. Standar are also kept at the Tower, particularly for troy weigh By these regulations a uniformity of weights and measures is established throughout the kingdom; but measures of capacity, particularly those for corn, vary considerably in different places.

In the year 1758, a committee of the House of Commons was appointed, to inquire into the standards of English weights and measures. It was composed chiefly men of science; who were assisted in their researches several eminent mathematicians and mechanists. T report of this committee, which is printed in the minu of the house, contains the most full and authentic statement of the English weights and measures perhaps e published; and as no alteration in them has since tak place, the substance of the report is here given, with so account of the proceedings of the committee.

From the report it appears, that the subdivisions of original standards, at the Exchequer and at Guildhall, not perfectly agree in their various combinations. Th differences however are very small, and are of the less importance, as the principal standards of long measures a of weights are sufficiently correct.

With respect to the measures of capacity, considera differences were found to exist in the subdivisions; as w as a great diversity in the corn bushel in different parts the kingdom, notwithstanding the numerous acts of parliament which had been passed to enforce uniformity. all these acts, the Winchester bushel is stated to be only legal one. This is the bushel now used at the port of London, at Mark-lane, and at Guildhall; and yet it does not exactly agree, either in shape or contents, with the standard bushel at the Exchequer.

As to the different kinds of weights, the committee recommended that the troy pound should be made the unit or standard, by which the avoirdupois and other weights should be regulated; because it is the weight best known to our laws, and that which has been longest in use; that by which our coins are weighed, and which is best known to the rest of the world; that to which our learned countrymen have referred, in comparing ancient and modern weights; and that which has been divided into the smallest proportions or parts.

Indeed this pound (called by the Romans the pondus or weight, and also the libra or balance,) is the most general standard or unit for weights, as the foot is for measures; and it is remarkable that both have been divided into the same number of equal parts, and that their divisions were anciently called by the same name, uncia, which signifies the 12th part of a whole. Hence, the ounce and inch have one common derivation, the former being called uncia libræ, and the latter uncia pedis.

The committee, having found some variations in the divisions and multiples of the standard troy pound at the Tower, caused it to be divided into halves, quarters, eighths, &c, down to the 1000th part of a grain. These divisions were made with so much accuracy, as to answer their due proportions in every possible combination; and for the purpose of ascertaining them with the greatest correctness, a very curious weighing apparatus was constructed by Mr. Bird, which is still carefully preserved in the Mint. It is adapted to five different beams, which ascertain the weights from 12 ounces down to 1 grain, and with so much exactness as to discern an error to the 2000th part of a grain. By this apparatus it has been found that the brass standard avoirdupois pound, kept in the Mint, weighed exactly 7000 grains; and it was further ascertained that this pound perfectly agreed with the bell standard pound (of 1588) at the Exchequer, and also with the bell standard pound at Guildhall.

The Royal Society of London have paid very laudable attention to the subject of weights and measures, at different periods, particularly in 1768, under the management of Dr. Maskelyne the astronomer-royal, and in 1798, under that of Sir George Shuckburgh; as may be seen in the Philos. Trans. of those years. And the same has been done by the Society of Arts in London, as before noticed. In 1802, M. Pictet, professor of philosophy at Geneva, made the following trials of the different English standards of length, by a scale constructed with great accuracy by Mr. Troughton, of London; and by means of a comparer made by the same ingenious artist, capable of showing differences to the 10,000th part of an inch. The following results were from trials made on several standard yards, in the temperature of 62° of Fahrenheit's thermometer.

	Inches.
Parliamentary standard of 1758, by Bird	36·00023
Royal Society's ditto, also made by Bird	35·99955
Ditto, by Mr. Graham - - -	36·00130
Exchequer standard - - - -	35·99380
Tower standard - - - - -	36·00400
General Roy's do. (for the trigon. survey)	36·00036

The above statement was presented by M. Pictet to the National Institute of France; when, by several trials with the same apparatus, the new French metre was found to be 39·371 English inches, which in 1800 had been found by the Royal Society of London to be 39·3702, from a comparison with two toises sent by M. Lalande to Dr. Maskelyne. See the article WEIGHTS, also Kelly's Universal Cambist.

In the spring of the year 1814, the English parliament again took into consideration the forming general standards of uniform measures and weights, which might be conveniently used in all the British dominions. For this purpose, a committee of their members was appointed, who, after consulting and examining some learned scientific men, delivered in their report, the results of which are the following:

1. The committee recommended that the brass standard yard kept in the Court of Exchequer should be adopted and considered as the original standard measure; as divided into 3 feet, and each foot into 12 inches, or the yard 36 inches.—2. The committee then assert that the simple pendulum vibrating seconds in the latitude of London, in the temperature of 56½ degrees of Fahrenheit's thermometer, has been found to measure 39·13 such inches.—3. That a cubical foot of pure or distilled water weighs just 1000 ounces avoirdupois; and that therefore the avoirdupois weight will be the most convenient to adopt for the general weight of the country, the pound being divided into 16 ounces, and the ounce into 16 drachms. That, as a cubical foot of water weighs 1000 ounces, therefore, by proportion, the pound or 16 ounces of water will contain 27·648 cubic inches; from which all other weights, above and below the pound, are to be estimated proportionally.—4. That, as the standard weights are thus derived from the lineal measures, so the measures of capacity are recommended to be derived from the standard weights, in this manner; viz, that the gallon measure shall contain 10 pounds weight of water; consequently that the table of measures of capacity will be as follows:

The gallon of 10 lb.		=	276·48 cubic inches.
The bushel = 8 gallons	= 80 lb.	=	2211·84 cub. inch.
The quart = ¼ gallon	= 40 oz.	=	69·12 cub. inch.
The pint = ⅛ gallon	= 20 oz.	=	34·56 cub. inch.
The half pint	= 10 oz.	=	17·28 cub. in. or $\frac{1}{100}$ of a cub. ft.

For the committee's report at large, see the Philosophical Magazine, vol. 44, pa. 171.

The several measures used in England, are as in the following tables:

1. *English Long Measure.*

Barley Corns						
3 =	1 Inch					
36 =	12 =	1 Foot				
108 =	36 =	3 =	1 Yard			
594 =	198 =	16½ =	5½ =	1 Pole		
23760 =	7920 =	660 =	220 =	40 =	1 Furlong	
190082 =	63360 =	5280 =	1760 =	320 =	8 =	1 Mile

Also, 4 Inches = 1 Hand
6 Feet, or 2 yds = 1 Fathom
3 Miles = 1 League
60 Nautical or Geograph. Miles = 1 Degree
or $69\frac{1}{13}$ Statute Miles = 1 Degree nearly
360 Degrees, or 24,864 Miles nearly = the circumference of the meridian.

2. *Cloth Measure.*

Inches				
2¼ =	1 Nail			
9 =	4 =	1 Quarter		
36 =	16 =	4 =	1 Yard	
27 =	12 =	3 =	1 Ell Flemish	
45 =	20 =	5 =	1 Ell English	
54 =	24 =	6 =	1 Ell French.	

3. *Square Measure.*

Inches					
144 =	1 Foot				
1296 =	9 =	1 Yard			
39204 =	272¼ =	30¼ =	1 Pole		
1568160 =	10890 =	1210 =	40 =	1 Rood	
6272640 =	43560 =	4840 =	160 =	4 =	1 Acre.

4. *Solid*, or *Cubical Measure.*

Inches		
1728 =	1 Foot	
46656 =	27 =	1 Yard

5. *Wine Measure.*

Pints							
2 =	1 Quart						
8 =	4 =	1 Gallon = 231 Cubic Inches					
336 =	168 =	42 =	1 Tierce				
504 =	252 =	63 =	1½ =	1 Hogshead			
672 =	336 =	84 =	2 =	1⅓ =	1 Puncheon		
1008 =	504 =	126 =	3 =	2 =	1½ =	1 Pipe	
2016 =	1008 =	252 =	6 =	4 =	3 =	2 =	1 Tun.

Also, 231 Cubic Inches = 1 Gallon
10 Gallons = 1 Anker
18 Gallons = 1 Runlet
31½ Gallons = 1 Barrel.

6. *Ale and Beer Measure.*

Pints								
2 =	1 Quart							
8 =	4 =	1 Gallon = 282 Cubic Inches						
72 =	36 =	9 =	1 Firkin					
144 =	72 =	18 =	2 =	1 Kilderkin				
288 =	144 =	36 =	4 =	2 =	1 Barrel			
432 =	216 =	54 =	6 =	3 =	1½ =	1 Hogshead		
576 =	288 =	72 =	8 =	4 =	2 =	1⅓ =	1 Puncheon	
864 =	432 =	108 =	12 =	6 =	3 =	2 =	1½ =	1 But

Note, The Ale gallon contains 282 inches.

7. *Dry Measure.*

Pints							
8 =	1 Gallon = 268⅘ Cubic Inches						
16 =	2 =	1 Peck					
64 =	8 =	4 =	1 Bushel				
256 =	32 =	16 =	4 =	1 Coom			
512 =	64 =	32 =	8 =	2 =	1 Quarter		
2560 =	320 =	160 =	40 =	10 =	5 =	1 Wey	
5120 =	640 =	320 =	80 =	20 =	10 =	2 =	1 Last.

Also, 268⅘ Cubic Inches = 1 Gallon.
and 36 Bushels of Coals = 1 Chaldron.

8. *Proportion of the Long Measures of several Nations to the English Foot.*

MEASURING, the same as MENSURATION.

MECHAIN (PIERRE-FRANÇOIS-ANDRÉ), a member of the National Institute, and of the Board of Longitude, F. R. S. Lond. &c, was born at Laon, in the department of Aisne, April 16, 1744, and died in the province of Valencia in Spain, of an epidemic disorder, as he was prosecuting the measurement of an arc of the meridian, Sept. 20, 1805.—Having shown at an early age a good taste for mathematics, Mechain was sent to Paris, where he was patronized by M. Lalande, was entered in the depôt of the marine, and afterwards made two voyages with M. Bretonniere, to survey the coasts of France from Neuport to St. Maloes. The first memoirs which made him known as an astronomer, were on the occultation of Aldebaran, which had been observed in 1744, on the great eclipse of the sun in 1778, and on the opposition of Jupiter in 1779. After this period, he rapidly advanced to celebrity, became in 1782 a member of the French Academy, and in 1785 was intrusted with the direction of the Connoissance des Temps, the volumes of which, from 1788 to 1794, were greatly enriched by his memoirs —He was also united with MM. Cassini and Legendre in measuring a series of triangles, to correspond with those of the English mathematicians, for the purpose of rectifying the relative positions of the observatories of Greenwich and Paris; of which Mechain gave details in the Memoirs of the Academy. When the Academy also was consulted by the Constituent Assembly, on the choice of a new system of measures, and proposed for the base of this measure, a quarter of the earth's meridian, the length of which arc was to be ascertained with the greatest possible exactness, M. Mechain was one of those who were appointed to this important undertaking. The arc proposed to be measured extended from Dunkirk to Barcelona, which he continued to labour upon till 1798, when he returned to Paris. But, to complete that work, he wished to continue it as far as the Balearic islands, for which purpose he set out again in 1803. He had already, with vast difficulty, revisited all the stations, and completed the observations at three of them, when he was cut off by a fever which prevails every year on the coast of Valencia, by reason of the morasses produced from the overflowing of the rivers.

In his character, M. Mechain is represented as remarkably modest and silent, seldom speaking at the meetings of the society. Before his last expedition it seems he intrusted to M. Delambre all his registers and manuscripts, extracts from which, it is said, will contribute more to Mechain's praise than the most eloquent oration.

MECHANICS, a mixed mathematical science, that treats of forces, motion, and moving powers, with their effects in machines, &c. The science of mechanics is distinguished, by Sir Isaac Newton, into practical and rational; the former treats of the mechanical powers, and of their various combinations; the latter, or rational mechanics, comprehends the whole theory and doctrine of forces, with the motions and effects produced by them.

That part of mechanics which treats of the weight, gravity, and equilibrium of bodies and powers, is called statics; as distinguished from that part which considers the mechanical powers, and their application, which is properly called mechanics.

Some of the principles of statics were established by Archimedes, in his Treatise on the Centre of Gravity of Plane Figures: besides which, little more on mechanics is to be found in the writings of the ancients, except what is contained in the 8th book of Pappus's Mathematical Collections, concerning the five mechanical powers. Galileo laid the best foundation of mechanics, when he investigated the descent of heavy bodies; and since his time, by the assistance of the new methods of computation, a great progress has been made, especially by Newton, in his Principia, which is a general treatise on rational and physical mechanics, in its largest extent. Other writers on this science, or some branch of it, are, Guido Ubaldus, in his Liber Mechanicorum; Torricelli, Libri de Motu Gravium naturaliter Descendentium et Projectorum; Balianus, Tractatus de Motu naturali Gravium; Huygens, Horologium Oscillatorium, and Tractatus de Motu Corporum ex Percussione; Leibnitz, Resistentia Solidorum, in Acta Eruditor. an. 1684; Guldinus, De Centro Gravitatis; Wallis, Tractatus de Mechanica; Varignon, Projet d'une Nouvelle Mechanique, and his papers in the Memoir. Acad. an. 1702; Borelli, Tractatus De Vi Percussionis, De Motionibus Naturalibus a Gravitate pendentibus, and De Motu Animalium; De Chales, Treatise on Motion; Pardies, Discourse of Local Motion; Parent, Elements of Mechanics and Physics; Casatus, Mechanica; Oughtred, Mechanical Institutions; Rohault, Tractatus de Mechanica; Lamy, Mechanique; Keill, Introduction to true Philosophy; Lahire, Mechanique; Mariotte, Traité du Choc des Corps; Ditton, Laws of Motion; Herman, Phoronomia; Gravesande, Physics; Euler, Tractatus de Motu; Musschenbroek, Physics; Bossut, Mechanique; Desaguliers, Mechanics; Rowning, Natural Philosophy; Emerson, Mechanics; Parkinson, Mechanics; Lagrange, Mechanique Analytique; Nicholson, Introduction to Natural Philosophy; Enfield, Institutes of Natural Philosophy, &c, &c As to the Description of Machines, see Strada, Zeisingius, Besson, Augustine de Ramellis, Boetler, Leopold, Sturmy, Perrault, Limberg, Emerson, Royal Academy of Sciences, Gregory's Mechanics, &c.

In treating of machines, we should consider the weight that is to be raised, the power by which it is to be raised, and the instrument or engine by which this effect is to be produced. And, in treating of these, there are two principal problems that present themselves: the first is, to determine the proportion which the power and weight ought to have to each other, that they may just be in equilibrio; the second is, to determine what ought to be the proportion between the power and weight, that a machine may produce the greatest effect in a given time. All writers on mechanics treat on the first of these problems; but few have considered the second, though not less useful than the other.

As to the first problem, this general rule holds in all powers, namely, that when the power and weight are reciprocally proportional to the distances of the directions in which they act, from the centre of motion; or when the product of the power by the distance of its direction, is equal to the product of the weight by the distance of its direction; this is the case in which the power and weight sustain each other, and are in equilibrio; so that the one would not prevail over the other, if the engine were at rest; and if it were in motion, it would continue to proceed uniformly, if it were not for the friction of its parts, and other resistances. And, in general, the effect of any power, or force, is as the product of that force multiplied by the distance of its direction from the centre of motion, or the product of the power and its velocity when in motion, since this velocity is proportional to the distance from that centre.

Maximum effects of Machines.—This second general problem in mechanics, is, to determine the proportion between the power and weight, so that when the power prevails, and the machine is in motion, the greatest effect possible may be produced by it in a given time. It is manifest, that this is an inquiry of the greatest importance, though few have treated of it. When the power is only a little greater than what is sufficient to sustain the weight, the motion usually is too slow; and though a greater weight be raised in this case, it is not sufficient to compensate for the loss of time. On the other hand, when the power is much greater than what is sufficient to sustain the weight, this is raised in less time; but it may happen that this is not sufficient to compensate for the loss arising from the smallness of the load. It ought therefore to be determined when the product of the weight multiplied by its velocity, is the greatest possible; for this product measures the effect of the engine in a given time, which is always the greater in proportion both as the weight is greater, and as its velocity is greater. For some calculations on this problem, see Maclaurin's Account of Newton's Discoveries, pa. 171, &c; also his Fluxions, art. 908 &c; Gregory's Mechanics; also vol. 3 of my Course of Mathematics, chap. xi. And, for the various properties in mechanics, see the several terms Motion, Force, Mechanical Powers, Lever, &c.

MECHANIC, or Mechanical, something relating to mechanics, or regulated by the nature and laws of motion.

Mechanical is also used in mathematics, to signify a construction or proof of some problem, not done in an accurate and geometrical manner, but coarsely and unartfully, or by the assistance of instruments; as are most problems relating to the duplicature of the cube, and the quadrature of the circle.

Mechanical *Affections,* such properties in matter, as result from their figure, bulk, and motion.

Mechanical *Causes,* are such as are founded on Mechanical Affections.

Mechanical *Curve,* called also *Transcendental,* is one whose nature cannot be expressed by a finite algebraical equation.

Mechanical *Philosophy,* also called the *Corpuscular Philosophy,* is that which explains the phenomena of nature, and the operations of corporeal things, on the principles of mechanics; viz, the motion, gravity, figure, arrangement, disposition, greatness, or smallness of the parts which compose natural bodies.

Mechanical *Solution,* of a problem, is either when the thing is done by repeated trials, or when the lines used in the solution are not truly geometrical, or by organical construction.

Mechanical *Powers,* are certain simple machines which are used for raising greater weights, or overcoming greater resistances than could be effected by the natural strength without them.

These simple machines are usually accounted six in number, viz, the lever, the wheel-and-axle, or axis in peritrochio, the pulley, the inclined plane, the wedge, and the screw. Of the various combinations of these simple powers do all engines, or compound machines consist: and in treating of them, so as to settle their theory and properties, they are considered as mathematically exact, or void of weight and thickness, and moving without friction. See the properties and demonstrations of each of these under the several words Lever, &c. To which may be added the following general observations on them all, in a connective way.

1. A *Lever,* the most simple of all the mechanic powers, is an engine chiefly used to raise large weights to small heights; such as a handspike, when of wood; and a crow, when of iron. In theory, a lever is considered as an inflexible line, like the beam of a balance, and subject to the same proportions; only that the power applied to it, is commonly an animal power; and from the different ways of using it, or applying it, it is called a lever of the first, second, or third kind: viz, of the 1st kind, when the weight is on one side of the prop, and the power on the other; of the 2d kind, when the weight is between the prop and the power; and of the 3d kind, when the power is between the prop and the weight.

Many of the instruments in common use, are levers of one of the three kinds; thus, pincers, sheers, forceps, snuffers, and such like, are compounded of two levers of the first kind; for the joint about which they move, is the fulcrum, or centre of motion; the power is applied to the handles, to press them together; and the weight is the body which they pinch or cut. The cutting-knives used by druggists, patten-makers, block-makers, and some other trades, are levers of the 2d kind: for the knife is fixed by a ring at one end, which makes the fulcrum, or fixed point while the other end is moved by the hand, or power; and the body to be cut, or the resistance to be overcome, is th weight. Doors are levers of the 2d kind; the hinges bein the centre of motion; the hand applied to the lock is th power; while the door or weight lies between them. A pair of bellows consists of two levers of the 2d kind; th centre of motion is where the ends of the boards are fixe near the pipe; the power is applied at the handles; an the air pressed out from between the boards, by its re sistance, acts against the middle of the boards like a weigh The oars of a boat are levers of the 2d kind: the fixe point is the blade of the oar in the water; the power i the hand acting at the other end; and the weight to b moved is the boat. And the same of the rudder of vessel. Spring sheers and tongs are levers of the 3d kin where the centre of motion is at the bow-spring at on end; the weight or resistance is acted on by the oth end; and the hand or power is applied between the end A ladder raised by a man against a wall, is a lever of th 3d kind: and so are also almost all the bones and muscl of animals.

In all levers, the effect of any power or weight, is bot proportional to that power or weight, and also to i distance from the centre of motion. And hence it is tha in raising great weights by a lever, we choose the longe levers; and also rest it upon a point as far from the han or power, and as near to the weight, as possible. Henc also there will be an equilibrium between the power an weight, when those two products are equal, viz, the pow multiplied by its distance, equal to the weight multipli by its distance; that is, when the weight and power a to each other reciprocally as their distances from the fu crum or fixed parts.

2. *The Axis in Peritrochio,* or *Wheel and Axle,* is a sir ple engine consisting of a wheel fixed upon the end of axle, so that they both turn round together in the san time. This engine may be referred to the lever: for th centre of the axis, or wheel, is the fixed point; the radi of the wheel is the distance of the power, acting at t circumference of the wheel from that point; and th

radius of the axle is the distance of the weight from the same point. Hence the effect of the power, independent of its own natural intensity, is as the radius of the wheel; and the effect of the weight is as the radius of the axle: so that the two will be in equilibrio, when the two products are equal, which are made by multiplying each of these, the weight and power, by the radius, or distance at which it acts; and then also, the weight and power are reciprocally proportional to those radii.

In practice, the thickness of the rope, that winds upon the axle, and to which the weight is fastened, is to be considered: which is done, by adding half its thickness to the radius of the axis, for its distance from the fixed point, when there is only one fold of rope upon the axle; or as many times the thickness as there are folds, wanting only one half when there are several folds of the rope, one over another: which is the reason that more power must be applied when the axis is thus thickened; as often happens in drawing water from a deep and narrow well, over which a long axle cannot be placed.

If the rope to which the power is affixed, be successively applied to different wheels, whose diameters are larger and larger; the axis will be turned with still more and more ease, unless the intensity of the power be diminished in the same proportion; and if so, the axis will always be drawn with the same strength by a power continually diminishing: as is the case in spring clocks and watches; where the spiral spring, which is strongest in its action when first wound up, draws the fuzee, or continued axis in peritrochio, first by the smaller wheels, and as it unbends and becomes weak, acts upon the larger wheels, in such a manner that the machinery is always carried round with the same force.

As a small axis would be too weak for very great weights, and a large wheel would be not only expensive, but also inconvenient in its application, requiring more room than perhaps could be spared fot it; therefore, in order that the action of the power may be increased, without incurring either of those inconveniences, a compound axis in peritrochio is used, which is effected by combining wheels and axles by means of pinions, or small wheels, upon the axles, the teeth of which take hold of teeth made in the large wheels; as is seen in clocks, jacks, and other compound machines. And in such a combination of wheels and axles, the effect of the power is increased in the ratio of the continual product of all the axles, or small wheels, to that of all the large ones. Thus, if there be two small wheels and an axle, turning three large wheels; the axle being 2 inches diameter, and each of the small wheels 4 inches, while the large ones are 2 feet or 24 inches diameter; then $2 \times 4 \times 4 = 32$ is the continual product of the small diameters, and $24 \times 24 \times 24 = 13824$ is that of the large ones; therefore 13824 to 32, or 432 to 1, is the ratio in which the power is increased: and if the power be a man, whose natural strength is equal, suppose, to 150 pounds weight, then $432 \times 150 = 64800$lb, or 28ton 18cwt 64lb, is the weight he would be able to balance, suspended about the axle.

3. *A Single Pulley*, is a small wheel, moveable round an axis, called its centre pin; which of itself is not properly one of the mechanical powers, because it produces no mechanical advantage, except convenience; for as the weight hangs by one end of the cord that passes over the pulley, and the power acts at the other end of the same, these act at equal distances from the centre or axis of motion, and consequently the power is equal to the weight when in equilibrio. So that the chief use of the single pulley is to change the direction of the power from upwards to downwards, &c, and to convey bodies to a great height or distance, without a person moving from his place. —But by combining several single pulleys together a considerable gain of power is made, and that in proportion to the additional number of ropes made to pass over them; while it possesses at the same time the properties of a single pulley, by changing the direction of the action in any manner.

4. *The Inclined Plane*, is made by planks, bars, or beams, laid aslope; by which large and heavy bodies may be more easily raised or lowered, by sliding them up or down the plane; and the gain in power is in proportion as the length of the plane to its height, or as radius to the sine of the angle of inclination of the plane with the horizon.—In drawing a weight up an inclined plane, the power acts to the greatest advantage, when its direction is parallel to the plane.

5. *The Wedge*, which resembles a double inclined plane, is very useful to drive in below very heavy weights, to raise them but a small height, also in cleaving and splitting blocks of wood, and stone, &c; and the power gained, is in proportion of the slant side to half the thickness of the back. So that, if the back of a wedge be 2 inches thick, and the side 20 inches long, any weight pressing on the back will balance 20 times as much acting on the side. But the great advantage of a wedge lies in its being urged, not by pressure, but usually by percussion, as the blow of a hammer or mallet; by which means a wedge may be driven in below, and so be made to lift, almost any the greatest weight, as the largest ship, by a man striking the back of a wedge with a mallet.—To the wedge may be referred the axe or hatchet, the teeth of saws, the chisel, the auger, the spade and shovel, knives and swords of all kinds, as also the bodkin and needle, and in short all sorts of instruments which, beginning from edges or points, become gradually thicker as they lengthen; the manner in which the power is applied to such instruments, being different according to their different shapes, and the various uses for which they have been contrived.

6. *The Screw*, is a kind of perpetual or endless inclined plane; the power of which is still farther assisted by the addition of a handle or lever, where the power acts; so that the gain in power, is in the proportion of the circumference described or passed through by the power, to the distance between thread and thread in the screw.—The uses to which the screw is applied, are various; as, the pressing of bodies close together; such as the press for napkins, for bookbinders, for packers, hotpressers, &c.—In the screw, and the wedge, the power has to overcome both the weight, and also a very great friction in those machines; such indeed as amounts sometimes to as much as the weight to be raised, or more. But then this friction is of use in retaining the weight and machine in its place, even after the power is taken off.

If machines or engines could be made without friction, the least degree of power added to that which balances the weight, would be sufficient to raise it. In the lever, the friction is little or nothing; in the wheel-and-axle, it is but small; in pulleys, it is very considerable; and in the inclined plane, wedge, and screw, it is very great.

It is a general property in all the mechanical powers, that when the weight and power are regulated so as to balance each other, and if they be then put in motion, the power and weight will be to each other reciprocally as the velocities of their motion, or the power is to the weight as the velocity of the weight is to the velocity of the power; so that their two momenta are equal, viz, the product of the power multiplied by its velocity, equal to the product of the weight multiplied by its velocity. And hence too, universally, what is gained in power, is lost in time; for the weight moves as much slower as the power is larger.

Hence also it is plain, that the force of the power is not at all increased by engines; only the velocity of the weight, either in lifting or drawing, is so diminished by the application of the instrument, as that the momentum of the weight is not greater than the force of the power. Thus, for instance, if a force can raise a pound weight with a given velocity, it is impossible by the application of that force to any engine to raise 2 pounds weight with the same velocity: but it may be made to raise 2 pounds weight with half the velocity, or even 1000 times the weight with the 1000th part of the velocity.

See Maclaurin's Account of Newton's Philos. Discov. book 2, chap. 3; Hamilton's Philos. Ess. 1; Philos. Trans. 53, pa. 116; or Landen's Memoirs, vol. 1, pa. 1; or Gregory's Mechanics, vol. 1.

MECHANISM, either the construction or the machinery employed in any thing; as the mechanism of the barometer, of the microscope, &c.

MEDIETATES, a term greatly used by Pappus, and some other authors, for sets of proportionals, both arithmetical, geometrical, and harmonical. See Pappus, lib. 3, prop. 1 to prop. 27; also Viviani de Solidis Locis, lib. 3, pa. 81 to 100; and Blondel Resolution des 4 princip. Problemes d'Architecture, pa. 37.

MEDIUM, the same as Mean, either arithmetical, geometrical, or harmonical.

MEDIUM denotes also that space, or region, or fluid, &c, through which a body passes in its motion towards any point. Thus, the air, or atmosphere, is the medium in which birds and beasts live and move, and in which a projectile moves; water is the medium in which fishes move; and ether is a supposed subtile medium in which the planets move. Glass is also called a medium, being that through which the rays of light move and pass. Mediums resist the motion of bodies moving through them, in proportion to their density or specific gravity.

Subtile or *Ætherea*l MEDIUM, is an universal one, whose existence is by Newton rendered probable. He makes it universal; and vastly more rare, subtile, elastic, and active than air; and by that means freely permeating the pores and interstices of all other mediums, and diffusing itself through the whole creation. By the intervention of this subtile medium he thinks it is that most of the great phenomena of nature are effected. See ÆTHER.

This medium it would seem he has recourse to, as the first and most remote physical spring, and the ultimate of all natural causes: by the vibrations of this medium, he supposes that heat is propagated from lucid bodies; as also the intenseness of heat increased and preserved in hot bodies, and from them communicated to cold ones. By means of this medium, he supposes that light is reflected, inflected, refracted, and put alternately into fits of easy reflection and transmission; which effects he also elsewhere ascribes to the power of attraction; so that it would seem, the ethereal medium is the source and cause even of attraction itself.

Again, this medium being much rarer within the heavenly bodies, than in the heavenly spaces, and growing denser as it recedes farther from them, he supposes this is the cause of the gravitation of these bodies towards each other, and of the parts towards the bodies.

Again, from the vibrations of the same medium, excited in the bottom of the eye by the rays of light, and thence propagated through the capillaments of the optic nerves into the sensorium, he supposes that vision is performed: and so likewise hearing, from the vibrations of this or some other medium, excited in the auditory nerves by the tremors of the air, and propagated through the capillaments of those nerves into the sensorium: and so of the other senses.

And again, he conceives that muscular motion is performed by the vibrations of the same medium, excited in the brain at the command of the will, and thence propagated through the capillaments of the nerves into the muscles; and thus contracting and dilating them.

The elastic force of this medium, he shows, must be prodigiously great. Light moves at the rate of considerably more than 10 millions of miles in a minute; yet th vibrations and pulsations of this medium, to cause the fit of easy reflection and transmission, must be swifter tha light, which is yet 7 hundred thousand times swifter tha sound. Its elastic force therefore, in proportion to it density, must be above 490,000 million of times greate than the elastic force of the air, in proportion to its de sity; the velocities and pulses of the elastic mediun being in a subduplicate ratio of the elasticities, and th rarities of the mediums, taken together. And thus it ma be conceived that the vibration of this medium is the cau also of the elasticity of bodies.

Farther, the particles of which it is composed being su posed indefinitely small, even smaller than those of ligh if they be likewise supposed, like our air, endued with repelling power, by which they recede from each othe the smallness of the particles may exceedingly contribu to the increase of the repelling power, and consequently that of the elasticity and rarity of the medium; by th means fitting it for the free transmission of light, and t free motions of the heavenly bodies, in which the plan and comets may revolve without any considerable resi ance. If it be 700,000 times more elastic, and as ma times rarer, than air, its resistance will be above 600 m lion times less than that of water; a resistance that wou cause no sensible alteration in the motion of the plan in ten thousand years.

MEIBOMIUS (MARCUS), a very learned person, o family in Germany which had long been famous for learn men, was born at Helmstadt in 1590. He devot himself to literature and criticism, but particularly to t learning of the ancients; such as their music, the structu of their galleys, &c. In 1652 he published a collecti of seven Greek authors, who had written upon anci music, to which he added a Latin version by hims This work he dedicated to Queen Christina of Swede in consequence of which he received an invitation to t princess's court, like several other learned men, which accepted. The queen engaged him one day to sing an of ancient music, while a person danced the Greek dan to the sound of his voice; but the immoderate mi which this occasioned in the spectators, so covered h with ridicule, and disgusted him so vehemently, that abruptly left the court of Sweden immediately, a heartily battering with his fists the face of Bourdelot, the favourite physician and buffoon to the queen, who had persuaded her to exhibit that spectacle.

Meibomius pretended that the Hebrew copy of the Bible was full of errors, and undertook to correct them by means of a metre, which he fancied he had discovered in those ancient writings; but this it seems drew upon him no small raillery from the learned. Nevertheless, besides the work above mentioned, he produced several others, which showed him to be a good scholar; witness his Notes upon Diogenes Laertius in Menage's edition; his Liber de Fabrica Triremium, 1671, in which he thinks he discovered the method in which the ancients disposed their banks of oars; his edition of the Ancient Greek Mythologists; and his Dialogues on Proportions, a curious work, in which the interlocutors, or persons represented as speaking, are Euclid, Archimedes, Apollonius, Pappus, Eutocius, Theo, and Hermotimus. This last work was opposed by Langius, and by Dr. Wallis, in a considerable tract, printed in the first volume of his works. Meibomius died in 1668.

MELODY, is the agreeable effect of different musical sounds, ranged or disposed in a proper succession, being the effect only of one single part, voice, or instrument; by which it is distinguished from harmony, which properly results from the union of two or more musical sounds heard together.

MENISCUS, a lens or glass, convex on one side, and concave on the other. Sometimes also called a lune or lunula. See its figure under the article LENS.

To find the Focus of a Meniscus, the rule is, as the difference between the diameters of the convexity and concavity, is to either of them, so is the other diameter, to the focal length, or distance of the focus from the meniscus. So that, having given the diameter of the convexity, it is easy to find that of the concavity, so as to remove the focus to any proposed distance from the meniscus. For, if D and d be the diameters of the two sides, and f the focal distance; then since,

by the rule $D - d : D :: d : f$,
therefore $d : D :: f - d : f$,
or $f - d : f :: d : D$.

Hence, if D the diameter of the concavity be double to d that of the convexity, f will be equal to D, or the focal distance equal to the diameter; and therefore the meniscus will be equivalent to a plano-convex lens.—Again, if $D = 3d$, or the diameter of the concavity triple to that of the convexity, then will $f = \frac{1}{2}D$, or the focal distance equal to the radius of concavity; and therefore the meniscus will be equivalent to a lens equally convex on either side.—But if $D = 5d$, then will $f = \frac{1}{4}D$; and therefore the meniscus will be equivalent to a sphere.—Lastly, if $D = d$, then will f be infinite; and therefore a ray falling parallel to the axis, will still continue parallel to it after refraction.

MENSTRUUM, SOLVENT, or DISSOLVENT, any fluid that will dissolve hard bodies, or separate their parts. Sir Isaac Newton accounts for the action of menstruums from the acids with which they are impregnated; the particles of acids being endued with a strong attractive force, in which their activity consists, and by virtue of which they dissolve bodies. By this attraction they gather together about the particles of bodies, whether metallic, stony, or the like, and adhere very closely to them, so as scarce to be separated from them by distillation, or sublimation. Thus strongly attracting, and gathering together on all sides, they raise, disjoin, and shake asunder the particles of bodies, i. e. they dissolve them; and by the attractive power with which they rush against the particles of the bodies, they move the fluid, and so excite heat, shaking some of the particles to that degree, as to convert them into air, and so generating bubbles.

Dr. Keill has given the theory or foundation of the action of menstruums, in several propositions. See ATTRACTION. From those propositions are perceived the reasons of the different effects of different menstruums; why some bodies, as metals, dissolve in a saline menstruum; others again, as resins, in a sulphureous one; &c: particularly why silver dissolves in aqua fortis, and gold only in aqua regis; all the varieties of which are accounted for, from the different degrees of cohesion, or attraction in the parts of the body to be dissolved, the different diameters and figures of its pores, the different degrees of attraction in the menstruum, and the different diameters and figures of its parts.

MENSURABILITY, the fitness of a body for being applied, or conformable to a certain measure.

MENSURATION, the act, or art, of measuring figured extension and bodies; or of finding the dimensions and contents of bodies, both superficial and solid.

Every different species of mensuration is estimated and measured by others of the same kind: so, the solid contents of bodies are measured by cubes, as cubic inches, or cubic feet, &c; surfaces by squares, as square inches, feet, &c; and lengths or distances by other lines, as inches, feet, &c.

The contents of rectilinear figures, whether plane or solid, can be accurately determined, or expressed; but of many curved ones, this is not possible. So the quadrature of the circle, and cubature of the sphere, are problems that have never yet been accurately solved. See the various kinds of mensuration, as well as that of the different figures, under their respective terms.

The first writers on geometry were chiefly writers on mensuration; as Euclid, Archimedes, &c. See QUADRATURE; also the Preface to my Mensuration, for more ample information on this subject.

MERCATOR (GERARD), an eminent geographer and mathematician, was born in 1512, at Ruremonde in the Low-Countries. He applied himself with such industry to the sciences of geography and mathematics, that it has been said he often forgot to eat and sleep. The emperor Charles the 5th encouraged him much in his labours; and the duke of Juliers made him his cosmographer. He composed and published a Chronology; a large and small Atlas; and some Geographical Tables; besides some books in philosophy and divinity. He was also so curious, as well as ingenious, that he engraved and coloured his maps himself. He made various maps, globes, and other mathematical instruments for the use of the emperor; and gave the most ample proofs of his uncommon skill in what he professed. His method of laying down charts is still used, which bear the name of Mercator's Charts; also a part of navigation is from him called Mercator's Sailing.—He died at Duisbourg in 1594, at 82 years of age.—See MERCATOR'S *Chart*, below.

MERCATOR (*Nicholas*), an eminent mathematician and astronomer, whose name in High-Dutch was Hauffman, was born, about the year 1640, at Holstein in Denmark. From his works we learn, that he had an early and liberal education, suitable to his distinguished genius, by which he was enabled to extend his researches into the mathematical sciences, and to make very considerable improvements: for it appears from his writings, as well as from the character given of him by other mathematicians, that his talent rather lay in improving, and adapting any discoveries and improvements to use, than invention. However, his genius for the mathematical sciences was very conspicuous, and introduced him to public regard and esteem in his own country, and facilitated a correspondence with such as were eminent in those sciences, in Denmark, Italy, and England. Some of his correspondents gave him an invitation to this country, which he accepted, and he afterwards continued in England till his death. He had not been long here before he was admitted F. R. S. and gave frequent proofs of his close application to study, as well as of his eminent abilities in improving some branch or other of the sciences. But he is charged sometimes with borrowing the inventions of others, and adopting them as his own. And it appeared on some occasions, that he was not of an over liberal mind in scientific communications. Thus, it had some time before him been observed, that there was an analogy between a scale of logarithmic tangents and Wright's protraction of the nautical meridian line, which consisted of the sums of the secants; though it does not appear by whom this analogy was first discovered. It appears however to have been first published, and introduced into the practice of navigation, by Henry Bond, who mentions this property in an edition of Norwood's Epitome of Navigation, printed about 1645; and he again treats of it more fully in an edition of Gunter's Works, printed in 1653, where he teaches, from this property, to resolve all the cases of Mercator's Sailing by the logarithmic tangents, independent of the table of meridional parts. This analogy had only been found to be nearly true by trials, but not demonstrated to be a mathematical property. Such demonstration seems to have been first discovered by Mercator, who, desirous of making the most advantage of this and another concealed invention of his in navigation, by a paper in the Philosophical Transactions for June 4, 1666, invites the public to enter into a wager with him, on his ability to prove the truth or falsehood of the supposed analogy. This mercenary proposal it seems was not taken up by any one, and Mercator reserved his demonstration. Our author however distinguished himself by many valuable pieces on philosophical and mathematical subjects. His first attempt was, to reduce astrology to rational principles, which proved a vain attempt. But his writings of more particular note, are as follow:

1. Cosmographia, sive Descriptio Cœli et Terræ in Circulos, qua fundamentum sternitur sequentibus ordine Trigonometriæ Sphericorum Logarithmicæ, &c, a Nicolao Hauffman Holsato; printed at Dantzic, 1651, 12mo.

2. Rationes Mathematicæ subductæ anno 1653; Copenhagen, in 4to.

3. De Emendatione annua Diatribæ duæ, quibus exponuntur et demonstrantur Cycli Solis et Lunæ, &c; in 4to.

4. Hypothesis Astronomica nova, et Consensus ejus cum Observationibus; Lond. 1664, in folio.

5. Logarithmotechnia, sive Methodus Construendi Logarithmos nova, accurata, et facilis; scripto antehac communicata anno sc. 1667 nonis Augusti; cui nunc accedit, Vera Quadratura Hyperbolæ, et Inventio summæ Logarithmorum. Auctore Nicolao Mercatore Holsato è Societate Regia. Huic etiam jungitur Michaelis Angeli Riccii Exercitatio Geometrica de Maximis et Minimis, hic ob argumenti præstantiam et exemplarium raritatem recusa; Lond. 1668, in 4to.

6. Institutionum Astronomicarum libri duo, de Motu Astrorum communi et proprio, secundum hypotheses veterum et recentiorum præcipuas; deque Hypotheseon ex observatis constructione, cum tabulis Tychonianis, Solaribus, Lunaribus, Lunæ-solaribus, et Rudolphinis Solis, Fixarum et quinque Errantium, earumque usu præceptis et exemplis commonstrato. Quibus accedit Appendix de iis, quæ novissimis temporibus cœlitus innotuerunt; Lond. 1676, 8vo.

7. Euclidis Elementa Geometrica, novo ordine ac methodo fere, demonstrata. Una cum Nic. Mercatoris in Geometriam Introductione brevi, qua Magnitudinum Ortus ex genuinis Principiis, et Ortarum Affectiones ex ipsa Genesi derivantur. Lond. 1678, 12mo.

His papers in the Philosophical Transactions, are,

1. A Problem on some Points in Navigation: vol. 1.
2. Illustrations of the Logarithmo-technia: vol. 3.
3. Considerations concerning his Geometrical and Direct Method for finding the Apogees, Excentricities, and Anomalies of the Planets: vol. 5, pa. 1168.

Mercator died in 1694, about 54 years of age.

MERCATOR'S *Chart*, or *Projection*, is a projection of the surface of the earth in plano, so called from Gerrard Mercator, a Flemish geographer, who first published maps of this sort in the year 1556; though it was Edward Wright who first gave the true principles of such charts, with their application to navigation, in 1699.

In this chart or projection, the meridians, parallels, and rhumbs, are all straight lines, the degrees of longitude being every-where increased so as to be equal to one another, and having the degrees of latitude also increased in the same proportion; namely, at every latitude or point on the globe, the degrees of latitude, and of longitude, or the parallels, are increased in the proportion of radius to the sine of the polar distance, or cosine of the latitude; or, which is the same thing, in the proportion of the secant of latitude to radius; a proportion which has the effect of representing the parallel circles by parallel and equal right lines, and all the meridians by parallel lines also, but increasing infinitely towards the poles.

From this proportion of the increase of the degrees of the meridian, viz, that they increase as the secant of the latitude, it is very evident that the length of an arch of the meridian, beginning at the equator, is proportional to the sum of all the secants of the latitude, i.e. that the increased meridian, is to the true arch of it, as the sum of all those secants, to as many times the radius. But it is not so evident that the same increased meridian is also analogous to a scale of the logarithmic tangents, which however it is. "It does not appear by whom, nor by what accident, the analogy was discovered between a scale of logarithmic tangents and Wright's protraction of the nautical meridian line, which consisted of the sums of the secants. It appears however to have been first published and introduced into the practice of navigation, by Mr. Henry Bond, who mentions this property in an edition of Norwood's Epitome of Navigation, printed about 1645; and he again treats of it more fully in an edition of Gunter's Works, printed in 1653, where he teaches, from this property, to resolve all the cases of Mercator's Sailing by the logarithmic tangents, independent of the table of meridional parts. This analogy had only been found however to be nearly true by trials, but not demonstrated to be a mathematical property. Such demonstration, it seems, was first discovered by Mr. Nicholas Mercator, which he offered a wager to disclose; but this not being accepted, Mercator reserved his demonstration; as mentioned in the account of his life in the foregoing page. The proposal however excited the attention of mathematicians to the subject, and demonstrations were not long wanting. The first was published about 2 years after, by James Gregory, in his Exercitationes Geometricæ; from hence, and other similar properties there demonstrated, he shows how the tables of logarithmic tangents and secants may easily be computed from the natural tangents and secants.

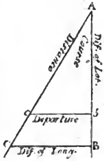
" The same analogy between the logarithmic tangents and the meridian line, as also other similar properties, were afterwards more elegantly demonstrated by Dr. Halley, in the Philos. Trans. for Feb. 1696, and various methods given for computing the same, by examining the nature of the spirals into which the rhumbs are transformed in the stereographic projection of the sphere on the plane of the equator: the doctrine of which was rendered still more easy and elegant by the ingenious Mr. Cotes, in his Logometria, first printed in the Philos. Trans. for 1714, and afterwards in the collection of his works published 1732, by his cousin Dr. Robert Smith, who succeeded him as Plumian professor of philosophy in the university of Cambridge."

The learned Dr. Isaac Barrow also, in his Lectiones Geometricæ, Lect. xi, Append. first published in 1672, delivers a similar property, namely, " that the sum of all the secants of any arc, is analogous to the logarithm of the ratio of $r + s$ to $r - s$, viz, radius plus sine to radius minus sine; or, which is the same thing, that the meridional parts answering to any degree of latitude, are as the logarithms of the ratios of the versed sines of the distances from the two poles." Preface to my Logarithms, pa. 100.

The meridian line in Mercator's Chart, is a scale of logarithmic tangents of the half colatitudes. The differences of longitude on any rhumb, are the logarithms of the same tangents, but of a different species; those species being to each other, as the tangents of the angles made with the meridian. Hence any scale of logarithmic tangents is a table of the differences of longitude, to several latitudes, on some one determinate rhumb; and therefore, as the tangent of the angle of such a rhumb, is to the tangent of any other rhumb, so is the difference of the logarithms of any two tangents, to the difference of longitude on the proposed rhumb, intercepted between the two latitudes, of whose half complements the logarithmic tangents were taken.

It was the great study of our predecessors to contrive such a chart in plano, with straight lines, on which all, or any parts of the world, might be truly set down, according to their longitudes and latitudes, bearings and distances. A method for this purpose was hinted by Ptolemy, near 2000 years since; and a general map, on such an idea, was made by Mercator; but the principles were not demonstrated, and a ready way shown of describing the chart, till Wright explained how to enlarge the meridian line by the continual addition of secants; so that all degrees of longitude might be proportional to those of latitude, as on the globe: which renders this chart, in several respects, far more convenient for the navigator's use, than the globe itself; and which will truly show the course and distance from place to place, in all cases of sailing.

MERCATOR'S *Sailing*, or more properly *Wright's* Sailing, is the method of computing the cases of sailing on the principles of Mercator's chart, which principles were laid down by Edward Wright in the beginning of the 17th century; or the art of finding on a plane the motion of a ship upon any assigned course, that shall be true as well in longitude and latitude, as distance; the meridians being all parallel, and the parallels of latitude straight lines.



In the right-angled triangle *Abc*, let *Ab* be the true difference of latitude between two places, the angle *bAc* the angle of the course sailed, and *Ac* the true distance sailed; then will *bc* be what is called the departure, as in plane sailing: produce *Ab* till AB be equal to the meridional difference of latitude, and draw BC parallel to *bc*; so shall BC be the difference of longitude.

Now from the similarity of the two triangles *Abc*, ABC, when three of the parts are given, the rest may be found; as in the following analogies: As

Radius : sin. course : : distance : departure;
Radius : cos. course : : distance : dif. latitude;
Radius : tan. course : : merid. dif. lat : dif. longitude.

And by means of these analogies, all the cases of Mercator's Sailing may be resolved.

MERCURY, in Astronomy, the smallest of the inferior planets, and the nearest to the sun, about which it is carried with a very rapid motion. Hence it was, that the Greeks called this planet after the name of the nimble messenger of the gods, and represented it by the figure of a youth with wings at his head and feet; whence is derived ☿, the character in present use for denoting this planet.—The mean distance of Mercury from the sun, is to that of the earth from the sun, as 387 to 1000, and therefore his distance is about 37 millions of miles, or little more than one-third of the earth's distance from the sun. Hence the sun's diameter will appear at Mercury, near 3 times as large as at the earth; and hence also the sun's light and heat received there are about 7 times those at the earth; a degree of heat more than sufficient to make water boil. Such a degree of heat therefore must render Mercury not habitable to creatures of our constitution: and if bodies on its surface be not inflamed, and set on fire, it must be because their degree of density is proportionably greater than that of bodies on our globe.

The diameter of Mercury is also more than $\frac{1}{3}$ of the diameter of the earth, or about 3222 miles. Hence the surface of Mercury is nearly 1-9th, and his magnitude or bulk 1-27th of that of the earth.

The inclination of his orbit to the plane of the ecliptic, is 7° 0′; his period of revolution round the sun, 87 days 23 hours; his greatest elongation from the sun 28° 20′; the excentricity of his orbit $\frac{1}{4}$ of his mean distance, which is far greater than that of any of the other planets; and he moves in his orbit about the sun at the amazing rate of 95,000 miles an hour.

The place of his aphelion is ♐ 14° 32′; place of ascending node ♉ 14° 44′, and consequently that of the descending node ♏ 14° 44′. His length of day, or rotation on his axis, and inclination of axis to his orbit, are unknown.

Mercury changes his phases, like the moon, according to his various positions with regard to the earth and sun; except only, that he never appears quite full, because his enlightened side is never turned directly towards us, unless when he is so near the sun as to be lost to our sight in his beams. And as his enlightened side is always towards the sun, it is plain that he shines not by any light of his own; for if he did, he would constantly appear round.

The best observations of this planet are those made when it is seen on the sun's disc, called its transit; for in its lower conjunction, it sometimes passes before the sun like a little spot, eclipsing a small part of the sun's body, only observable with a telescope. That node from which Mercury ascends northward above the ecliptic, is in the 15th degree of Taurus, and the opposite in the 15th degree of Scorpio. The earth is in those parts on the 6th of November, and 4th of May, new style; and when Mercury comes to either of his nodes at his inferior conjunction about these times, he will appear in this manner to pass over the sun's disc. But in all other parts of his orbit, his conjunctions are invisible, because he goes either above or below the sun. The first observation of this kind was made by Gassendi, in November 1631. Several following observations of the like transits are collected in Du Hamel's Hist. of the Royal Acad. of Sciences, pa. 470, ed. 2. And Mr. Whiston has given a list of several periods at which Mercury may be seen on the sun's disc, viz, in 1782, Nov. 12, at $3^h\ 44^m$ afternoon; in 1786, May 4th, at $6^h\ 57^m$ in the forenoon; in 1789, Dec. 6th, at $3^h\ 55^m$ afternoon; and in 1799, May 7th, at 2° 34^m afternoon. There are also several intermediate transits, but none of them visible at London. See Dr. Halley's account of the Transits of Mercury and Venus, in the Philos. Trans. No. 193.

MERCURY, a metal of a silvery white colour, and is otherwise called quicksilver. This metal is always fluid at the usual temperature of the atmosphere, but freezes and becomes fixed at the temperature of −39° of Fahrenheit's thermometer, that is 39° below 0, or 71° below the freezing point of water; and it contracts about $\frac{1}{23}$ of its bulk in the moment of freezing. Its boiling point is 660°; it may therefore be totally evaporated, or distilled from one vessel into another, by which means it is purified from various other metallic matters. The vapour of mercury is invisible, and elastic, like common air; like air too, its elasticity is indefinitely increased by heat, so that it breaks the strongest vessel, with an explosion as loud as a cannon.

MERIDIAN, in Astronomy, is a great circle of the celestial sphere, passing through the poles of the world, and both the zenith and nadir, crossing the equinoctial at right angles, and dividing the sphere into two equal parts, or hemispheres, the one eastern, and the other western. Or, the meridian is a vertical circle passing through the poles of the world.—It is called meridian, from the Latin Meridies, mid-day or noon, because when the sun comes to the south part of this circle, it is noon to all those places situated under it.

MERIDIAN, in Geography, is a great circle passing through the north and south poles, and any given place: thus, the meridian of London, is that circle which passes over London and through the poles of the earth; and it lies exactly under, or in the plane of, the celestial meridian.—These meridians are various, and change according to the longitude of places; so that their number may be said to be infinite, since all places from east to west have their several meridians. Farther, as the meridian invests the whole earth, there are many places situated under the same meridian. Also, as it is noon whenever the centre of the sun is in the celestial meridian; and as the meridian of the earth is in the plane of the former; it follows, that it is noon at the same time, in all places situated under the same meridian.

First MERIDIAN, is that from which the rest are counted, reckoning both east and west, and is the beginning of longitude. The fixing of the first meridian, is a matter merely arbitrary; and hence different persons, nations, and ages, have fixed it differently: from which circumstance some confusion has arisen in geography. The rule among the ancients was, to make it pass through the place farthest to the west that was known. But the moderns knowing that there is no such place on the earth as can be esteemed the most westerly, the way of computing the longitudes of places from one fixed point is much laid aside.

Ptolemy assumed the meridian that passes through the farthest of the Canary Islands, as his first meridian; that being the most western place of the world then known. After him, as more countries were discovered in that quarter, the first meridian was removed farther off. The Arabian geographers chose to place the first meridian on the utmost shore of the western ocean. Some fixed it to the island of St. Nicholas near the Cape Verd; Hondius to the isle of St. James; others to the island of Del Corvo, one of the Azores; because on that island the magnetic needle at that time pointed directly north, without any variation; and it was not then known that the variation of the needle is itself subject to variation. The latest geographers, particularly the Dutch, have pitched on the Peak of Teneriffe; others on the Isle of Palm, another of the Canaries; and lastly, the French, by order of the king, on the island of Fero, another of the Canaries.

But, without much regard to any of these rules, geographers and constructors of maps often assume the meridian of the place where they live, or the capital of their country, or its chief observatory, for a first meridian; and from it reckon the longitudes of places, east and west.

Astronomers, in their calculations, usually choose the meridian of the place where their observations are made, for their first meridian: as Ptolemy at Alexandria; Tycho Brahé at Uranibourg; Riccioli at Bologna; Flamsteed at the Royal Observatory at Greenwich; and the French at the observatory at Paris.

There is a suggestion in the Philos. Trans. that the meridians vary in time. And it has been said that this is rendered probable, from the old meridian line in the church of St. Petronio at Bologna, which is said to vary no less than 8 degrees from the true meridian of the place at this time: and from the meridian of Tycho at Uranibourg, which M. Picart observes, varies 18 minutes from the modern meridian. If there be any thing of truth in this hint, Dr. Wallis says, the alteration must arise from a change of the terrestrial poles (here on earth, of the earth's diurnal motion), not of their pointing to this or that of the fixed stars: for if the poles of the diurnal motion remain fixed to the same place on the earth, the meridians, which pass through these poles, must remain the same.

But the notion of the changes of the meridian seems to be much weakened by an observation of M. Chazelles, of the French Academy of Sciences, who, when in Egypt, found that the four sides of a pyramid, built 3000 years ago, still pointed very exactly to the four cardinal points: a position which cannot be considered as merely fortuitous. But here again it may be asked, If the meridians vary, may it not be by an oscillatory motion, similar to that of the variation of the magnetic needle, so that at a distance of 3000 years, the observations made in any particular place may agree, though during that period a constant and successive variation may have taken place, vibrating as it were between certain limits, as is now generally known to be the case in other planetary variations, such as the acceleration of the moon, the variation in obliquity of the ecliptic to the equator, &c. And under this point of view the observation of Chazelles would not affect the truth of the other assertions. For measuring an arc of the meridian, see the article DEGREE.

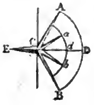
MERIDIAN *of a Globe*, or *Sphere*, is the brazen circle, in which the globe hangs and turns. It is divided into four 90's, or 360 degrees, beginning at the equinoctial: on it, each way, from the equinoctial, on the celestial globes, is counted the north and south declination of the sun, moon, or stars; and on the terrestrial globe, the latitude of places, north and south. There are two points on this circle called the poles; and a diameter, continued from thence through the centre of either globe, is called the axis of the earth, or heavens, on which it is supposed they revolve.

On the terrestrial globes there are usually drawn 36 meridians, one through every tenth degree of the equator, or through every 10th degree of longitude. The uses of this circle are, to set the globes, in any particular latitude, to show the sun's or a star's declination, right ascension, greatest altitude, &c.

MERIDIAN *Line*, an arch, or part, of the meridian of the place, terminated each way by the horizon. Or, a meridian line is the intersection of the plane of the meridian of the place with the plane of the horizon, often called a north-and-south line, because its direction is from north to south.

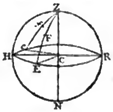
The meridian line is of most essential use in astronomy, geography, dialling, &c; and the greatest pains are taken by astronomers to fix it at their observatories to the utmost precision. M. Cassini has distinguished himself by a meridian line drawn on the pavement of the church of St. Petronio, at Bologna; being extended to 120 feet in length. In the roof of this church, 1000 inches above the pavement, is a small hole, through which the sun's image, when in the meridian, falling upon the line, marks his progress all the year. When finished, M. Cassini, by a public writing, quaintly informed the mathematicians of Europe, of a new oracle of Apollo, or the sun, established in a temple, which might be consulted, with entire confidence, as to all difficulties in astronomy. See GNOMON.

To draw a Meridian Line.—There are many ways of doing this; but some of the easiest and simplest are as follow: 1. On an horizontal plane describe several concentric circles AB, *ab*, &c; and on the common centre C erect a stile, or gnomon, perpendicular to the horizontal plane of about a foot in length. About the 21st of



June, between the hours of 9 and 11 in the morning, and between 1 and 3 in the afternoon, observe the points A, *a*, B, *b*, &c, in the circles, where the shadow of the stile terminates. Bisect the arches AB, *ab*, &c, in D, *d*, &c. If then the same right line DE bisect all these arches, it will be the meridian line sought.—As it is not easy to determine precisely the extremity of the shadow, it will be best to make the stile flat at top, and to drill a small hole through it, noting the lucid point projected by it on the arches AB and *ab*, instead of marking the extremity of the shadow itself.

2. Another method is thus: Knowing the south quarter pretty nearly, observe the altitude FE of some star on the east side of it, and not far from the meridian HZRN: then keeping the quadrant firm on its axis, so as the plummet may still cut the same degree, direct it to the western side of the meridian, and wait till you find the star has the same altitude as before, as *fe*. Lastly, bisect the angle ECe, formed by the intersection of the two planes in which the quadrant has been placed at the time of the two observations, by the right line HR, which will be the meridian sought.



Many other methods are given by authors, of describing a meridian line; as by the pole star, or by equal altitudes of the sun, &c; by Schooten in his Exercitationes Geometricæ; Grey, Derham, &c, in the Philos. Trans. and by Ferguson in his Lectures on Select Subjects.

From what has been said it is evident that whenever the shadow of the stile covers the meridian line, the centre of the sun is in the meridian, and therefore it is then noon. And hence the use of a meridian line in adjusting the motion of clocks to the sun. If another stile be erected perpendicularly on any other horizontal plane, and a signal be given when the shadow of the former stile covers the meridian line drawn on another plane, noting the apex or extremity of the shadow projected by the second stile, a line drawn through that point and the foot of the stile will be a meridian line at the 2d place. Or, instead of the 2d stile, a plumb-line may be hung up, and its shadow noted on a plane, upon a signal given that the shadow of another plummet, or of a stile, falls exactly in another meridian line, at a little distance; which shadow will give the other meridian line parallel to the former.

MERIDIAN *Line*, on a dial, is a right line arising from the intersection of the meridian of the place with the plane of the dial. This is the line of noon, or 12 o'clock, and from hence the division of the hour-line begins.

MERIDIAN *Line*, on Gunter's Scale, is divided unequally towards 87 degrees, the same as the meridian in Mercator's chart is divided and numbered. This line is very useful in navigation. For, 1st, It serves to graduate a sea-chart according to the true projection. 2d, Being joined with a line of chords, it serves for the protraction and resolution of such rectilineal triangles as are concerned in latitude, longitude, course, and distance, in the practice of sailing; as also in pricking the chart truly at sea.

Magnetical MERIDIAN, is a great circle passing through or by the magnetical poles; to which meridians the magnetical needle conforms itself.

MERIDIAN *Altitude*, of the sun or stars, is their altitude when in the meridian of the place where they are observed.

MERIDIONAL *Distance*, in Navigation, is the same with the departure, or easting and westing, or distance between two meridians.

MERIDIONAL *Parts, Miles*, or *Minutes*, in Navigation, are the parts of the increased or enlarged meridian, in the Mercator's chart. Tables of these parts are found in most books of navigation; and they serve both for constructing that sort of charts, and for working that kind of navigation.

Under the article MERCATOR'S *Chart*, it is shown that the parts of the enlarged meridian increase in proportion as the cosine of the latitude to radius, or, which is the same thing, as radius to the secant of the latitude; and therefore it follows, that the whole length of the enlarged nautical meridian, from the equator to any point, or latitude, will be proportional to the sum of all the secants of the several latitudes up to that point of the meridian. And on this principle was the first table of meridional parts constructed, by the inventor of it, Mr. Edward Wright, and published in 1599; viz, he took the meridional parts

of $1' =$ the sec. of $1'$;
of $2' =$ sec. of $1'$ + sec. of $2'$;
of $3' =$ secants of 1, 2, and 3 min.
of $4' =$ secants of 1, 2, 3, and 4 min.

and so on by a constant addition of the secants.

The tables of meridional parts, so constructed, are perhaps exact enough for ordinary practice in navigation; but they would be more accurate if the meridian were divided into more or smaller parts than single minutes; and the smaller the parts, so much greater the accuracy. But, as a continual subdivision would greatly augment the labour of calculation, other ways of computing such a table have been devised, and treated of, by Bond, Gregory, Oughtred, Sir Jonas Moor, Dr. Wallis, Dr. Halley, and others. See MERCATOR'S *Chart*, and Robertson's Navigation, vol. 2, book 8. The best of these methods was derived from this property, viz. that the meridian line, in a Mercator's chart, is analogous to a scale of logarithmic tangents of half the complements of the latitudes; from which property also a method of computing the cases of Mercator's Sailing has been deduced, by Dr. Halley. Vide ut supra, also the Philos. Trans. vol. 46, pa. 559.

To find the MERIDIONAL PARTS *to any Spheroid, with the same exactness as in a Sphere.*

Let the semidiameter of the equator be to the distance of the centre from the focus of the generating ellipse, as m to 1. Let A represent the latitude for which the meridional parts are required, and s the sine of the latitude, to the radius 1: Find the arc B, whose sine is $\frac{s}{m}$; take the logarithmic tangent of half the complement of B, from the common tables; subtract the log. tangent from 10·0000000, or the log. tangent of 45°; multiply the remainder by the number 7915·7044679, and divide the product by m; then the quotient subtracted from the meridional parts in the sphere, computed in the usual manner for the latitude A, will give the meridional parts, expressed in minutes, for the same latitude in the spheroid, when it is the oblate one.

Example. If $m : 1 :: 1000 : 22$, then the greatest difference of the meridional parts in the sphere and spheroid is 76·0929 minutes. In other cases it is found by multiplying the remainder above mentioned by the nu[mber] 1174·078.

When the spheroid is oblong, the difference in th[e me]ridional parts between the sphere and spheroid, f[or the] same latitude, is then determined by a circular arc. [See] Philos. Trans. No. 461, sect. 14. Also Maclaurin's [Flux]ions, art 895, 899. And Murdoch's Mercator's Sailin[g].

MERLON, in Fortification, that part of the pa[rapet] which lies between two embrasures.

MERSENNE (MARTIN), a learned French au[thor], was born at Bourg of Oyse, in the province of M[aine], 1588. He studied at La Fleche at the same time [with] Descartes; with whom he contracted a strict friend[ship], which continued till death. He afterwards went to [Paris], and studied at the Sorbonne; and in 1611 entered hi[mself] among the Minims. He became well skilled in Heb[rew], philosophy, and mathematics. From 1615 to 1619 [he] taught philosophy and theology in the convent of Ne[vers], and became the superior of that convent. But being [de]sirous of applying himself more freely and closely to st[udy], he resigned all the posts he enjoyed in his order, and [re]tired to Paris, where he spent the remainder of his [life], excepting some short excursions which he occasion[ally] made into Italy, Germany, and the Netherlands.

Study and literary conversation were afterwards [his] whole employment. He held a correspondence with [most] of the learned men of his time; being as it were the [very] centre of communication between literary men o[f all] countries, by the mutual correspondence which he [ma]naged between them; being in France what Mr. Col[lins] was in England. He omitted no opportunity to eng[age] them to publish their works; and the world is oblige[d to] him for several excellent discoveries, which would pro[ba]bly have been lost, but for his encouragement; and [by] all accounts he had the reputation of being one of [the] best men, as well as philosophers, of his time. No p[er]son was more curious in penetrating into the secrets [of] nature, nor more anxious to bring all the arts and scien[ces] to perfection. He was the chief friend and literary ag[ent] of Descartes at Paris; giving him advice and assistance [on] all occasions, and informing him of all that passed [at] Paris and elsewhere. For, being a person of univer[sal] learning, but particularly excelling in physical and m[a]thematical knowledge, Descartes scarcely ever did a[ny] thing, or at least was not perfectly satisfied with a[ny] thing he had done, without first knowing what Mersen[ne] thought of it. It is even said, that when Mersenne ga[ve] out in Paris, that Descartes was erecting a new system [of] physics on the foundation of a vacuum, and found t[he] public very indifferent to it on that very account, he im[]mediately sent notice to Descartes, that a vacuum w[as] not then the fashion at Paris; upon which, that philos[o]pher changed his system, and adopted the old doctrine [of] a plenum.

Mersenne was a man of good invention also himsel[f], and he had a peculiar talent in forming curious question[s], though he did not always succeed in resolving them; how[]ever, he at least gave occasion to others to do it. It [is] said he invented the cycloid, otherwise called the roulett[e]. Presently the chief geometricians of the age engaged in th[e] contemplation of this new curve, among whom Mersenn[e] himself held a distinguished rank. After a very studiou[s] and useful life, he died at Paris in 1648, at 60 years of age.

Mersenne was author of many useful works, particularl[y] the following:

1. Questiones celeberrimæ in Genesim.
2. Harmonicorum Libri.
3. De Sonorum Natura, Causis, et Effectibus.
4. Cogitata Physico-Mathematica; 2 vols. 4to.
5. La Verité des Sciences.
6. Les Questions inouies.

Besides many letters in the works of Descartes and other authors.

MESOLABE, or MESOLABIUM, a mathematical instrument invented by the ancients, for finding two mean proportionals mechanically, which they could not perform geometrically. It consists of three parallelograms, moving in a groove to certain intersections. Its figure is described by Eutocius, in his Commentary on Archimedes. See also Pappus, lib. 3.

METEORIC *Stones*, or Aerolites, certain semi-metallic masses which sometimes fall from the atmosphere. See AEROLITE.

METEOROLOGY, is that part of physics which treats of the state of the weather, and the various phenomena of the atmosphere; such as hail, rain, snow, thunder, lightning, &c. Which see under the respective articles.

METIUS (ADRIAN), a native of Alcmaer, was professor of mathematics and medicine at Franeker, where he died in 1636. He was author of several mathematical works: as, 1. Doctrina Sphæricæ; 2. Astronomiæ universæ Institutio, 8vo; 3. Arithmeticæ et Geometricæ practica, 4to; 4. De Gemino usu utriusque Globi, 4to; 5. Geometrices per usum Circini nova praxis, 8vo.—The ratio 113 to 355, for the diameter to the circumference of a circle, is ascribed to this author.

METIUS (JAMES), brother to Adrian above-mentioned, who invented prospective glasses, or telescopes, one of which he presented to the States-General, in 1609. Tubes, with several pipes had long been used for directing the sight to distant objects, and rendering it more distinct; but those tubes were without glasses, and it seems it was James Metius who first added them. The story goes, that he discovered this method by chance, from seeing some school-boys playing on the ice, who used the covers of their copy-books for tubes, and having in sport placed bits of glass at the ends of these tubes, were much surprised to find, that distant objects, by that means, appeared nearer.

METO, or METON, the son of Pausanias, a famous mathematician of Athens, who flourished 432 years before Christ. In the first year of the 87th Olympiad, he observed the solstice at Athens: and published his Anneadecatoride, that is, his cycle of 19 years; by which he endeavoured to adjust the course of the sun to that of the moon, and to make the solar and lunar years begin at the same point of time. See CYCLE.

METONIC CYCLE, called also the Golden Number, and Lunar Cycle, or Cycle of the Moon, that which was invented by Meton the Athenian; being a period of 19 years. See CYCLE.

METOPE, or METOPA, in Architecture, the square space between the triglyphs of the Doric frize; which among the ancients used to be adorned with the heads of beasts, basons, vases, and other instruments used in sacrificing.

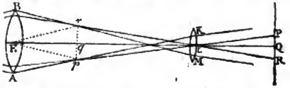
A *Demi-Metope* is a space somewhat less than half a metope, at the corner of the Doric frize.

MICHAELMAS, the feast of St. Michael the archangel; held on the 29th of September.

MICROCOUSTICS, the same with MICROPHONES.

MICROMETER, is an instrument usually fitted to a telescope, in the focus of the object-glass, for measuring small angles or distances; as the apparent diameters of the planets, &c. There are several kinds of these instruments, upon different principles; the origin of which has been disputed. The general principle is, that the instrument moves a fine wire parallel to itself, in the plane of the picture of an object, formed in the focus of a telescope, and so with great exactness to measure its perpendicular distance from a fixed wire in the same plane: and thus are measured small angles, subtended by remote objects at the naked eye.

For example. Let a planet be viewed through the telescope; and when the parallel wires are opened to such a distance as to appear exactly to touch two opposite points in the circumference of the planet, it is evident that the perpendicular distance between the wires is then equal to the diameter of the picture of the planet, formed in the focus of the object-glass. Let this distance, whose measure is given by the mechanism of the micrometer, be re-



presented by the line *pq*; then, since the measure of the focal distance *q*L may also be known, the ratio of *q*L to *qp*, that is, of radius to the tangent of the angle *q*L*p*, will give the angle itself, by a table of tangents; and this angle is equal to the opposite angle PQL, which the real diameter of the planet subtends at L, or at the naked eye.

With respect to the invention of the micrometer; Mess. Azout and Picard have the credit of it in common fame, as being the first who published it, in the year 1666; but Mr. Townley, in the Philos. Trans. reclaims it for one of our own countrymen, Mr. Gascoigne. He relates that, from some scattered papers and letters of this gentleman, he had learnt that before our civil wars he had invented a micrometer, of as much effect as that since made by M. Azout, and had made use of it for some years, not only in taking the diameters of the planets, and distances on land, but in determining other matters of nice importance in the heavens; as the moon's distance, &c. Mr. Gascoigne's instrument also fell into the hands of Mr. Townley, who says further, that by the help of it he could make above 40,000 divisions in a foot. This instrument being shown to Dr. Hooke, he gave a drawing and description of it, and proposed several improvements in it; which may be seen in the Philos. Trans. vol. 1, pa. 63. Mr. Gascoigne divided the image of an object, in the focus of the object-glass, by the approach of two pieces of metal, ground to a very fine edge; instead of which, Dr. Hooke would substitute two fine hairs, stretched parallel to each other: and two other methods of Dr. Hooke, different from this, are described in his posthumous works, pa. 497, &c. An account of several curious observations which Mr. Gascoigne made by the help of his micrometer, particularly in measuring the diameter of the moon and other planets, may be seen in the Philos. Trans. vol. 48, pa. 190; where Dr. Bevis refers to an original letter of Mr. Gascoigne, to Mr. Oughtred, written in 1641, for an account given by the author of his own invention, &c.

Mons. Lahire, in a discourse on the æra of the inventions of the micrometer, pendulum clock, and telescope, read before the Royal Academy of Sciences in 1717, makes M. Huygens the inventor of the micrometer. That author, he observes, in his Observations on Saturn's Ring, &c, published in 1659, gives a method of finding the diameters of the planets by means of a telescope, viz, by putting an object, which he calls a virgula, of a size proper to take in the distance to be measured, in the focus of the convex object-glass: in this case, says he, the smallest object will be seen very distinctly in that place of the glass. By such means, he adds, he measured the diameter of the planets, as he there delivers them. See Huygens's System of Saturn.

This micrometer, M. Lahire observes, is so very little different from that published by the Marquis De Malvasia, in his Ephemerides, 3 years after, that they ought to be esteemed the same: and the micrometer of the marquis differed yet less from that published 4 years after his, by Azout and Picard. Hence, Lahire concludes, that it is to Huygens the world is indebted for the invention of the micrometer; without taking any notice of the claim of our countryman Gascoigne, which however is many years prior to any of them.

Lahire says, that there is no method more simple or commodious for observing the digits of an eclipse, than a net in the focus of the telescope. These, he says, were usually made of silken threads; and for this particular purpose 6 concentric circles had also been used, drawn upon oiled paper: but he advises to draw the circles on very thin pieces of glass, with the point of a diamond. He also gives some particular directions to assist persons in using them. In another memoir, he shows a method of making use of the same net for all eclipses, by using a telescope with two object-glasses, and placing them at different distances from each other. Mem. 1701 and 1717.

M. Cassini invented a very ingenious method of ascertaining the right ascensions and declinations of stars, by fixing 4 cross hairs in the focus of the telescope, and turning it about its axis, so as to make them move in a line parallel to one of them. But the later improved micrometers will answer this purpose with greater exactness. Dr. Maskelyne has published directions for the use of it, extracted from Dr. Bradley's papers, in the Philos. Trans. vol. 62. See also Smith's Optics, vol 2, pa. 343.

Wolfius describes a micrometer of a very easy and simple structure, first contrived by Kirchius.

Dr. Derham tells us, that his micrometer is not put into a tube, as is usual, but is contrived to measure the spectres of the sun on paper, of any radius, or to measure any part of them. By this means he can easily, and very exactly, with the help of a fine thread, take the declination of a solar spot at any time of the day; and, by his half-seconds watch, measure the distance of the spot from either limb of the sun.

J. And. Segner proposed to enlarge the field of view in these micrometers, by making them of a considerable extent, and having a moveable eye-glass, or several eye-glasses, placed opposite to different parts of it. He thought however, that two would be quite sufficient, and he gives particular directions how to make use of such micrometers in astronomical observations. See Comm. Gotting. vol. 1, pa. 27.

A considerable improvement in the micromete[r was] communicated to the Royal Society, in 1743, by M[r.] Savary; an account of which, extracted from the mi[nutes] by Mr. Short, was published in the Philos. Tran[s.] 1753. The first hint of such a micrometer was sug[gested] by M. Roemer, in 1675: and M. Bouguer proposed a [con]struction similar to that of M. Savary, in 1748; for [which] see HELIOMETER. The late Mr. Dollond made a f[urther] improvement in this kind of micrometer, an accou[nt of] which was given to the Royal Society by Mr. Short[, and] published in the Philos. Trans. vol. 48. Instead o[f two] object-glasses, he used only one, which he neatly cu[t into] two semicircles, and fitted each semicircle in a [metal] frame, so that their diameters sliding in one anoth[er by] means of a screw, may have their centres brought tog[ether] in such a manner as to appear like one glass, and so [form] one image; or by their centres receding, may form [two] images of the same object: it being a property of [these] glasses, for any segment to exhibit a perfect image [of an] object, though not so bright as the whole glass would [make] it. If proper scales are fitted to this instrument, sh[owing] how far the centres recede, relative to the focal leng[th of] the glass, they will also show how far the two parts [of the] same object are asunder, relative to its distance fro[m the] object-glass; and consequently give the angle under w[hich] the distance of the parts of that object are seen. [This] divided object-glass micrometer, which was applie[d by] the late Mr. Dollond to the object end of a reflectin[g te]lescope, and has been with equal advantage adapte[d by] his son to the end of an achromatic telescope, is [of] easy use, and affords so large a scale, that it is gene[rally] considered by astronomers as the most convenient [and] exact instrument for measuring small angles in the [hea]vens. However, the common micrometer is pecul[iarly] adapted for measuring differences of right ascension[, and] declination, of celestial objects, but less convenient [and] exact for measuring their absolute distances; wherea[s the] object-glass micrometer is peculiarly fitted for meas[uring] distances, though generally supposed improper for [the] former purpose. But Dr. Maskelyne has found that [it] may be applied with very little trouble to that pur[pose] also; and he has furnished the directions necessary t[o be] followed, when it is used in this manner. The add[ition] requisite for this purpose, is a cell, containing two w[ires] intersecting each other at right angles, placed in the f[ocus] of the eye-glass of the telescope, and moveable abou[t by] the turning of a button. For the description of this [ap]paratus, with the method of applying and using it, see [Dr.] Maskelyne's paper on the subject, in the Philos. T[rans.] vol. 61, pa. 536, &c.

After all, the use of the object-glass micrometer i[s at]tended with many difficulties, arising from the alterat[ions] in the focus of the eye, which are apt to cause it to [give] different measures of the same angle at different times. [To] obviate these difficulties, Dr. Maskelyne, in 1776, [con]trived a prismatic micrometer, consisting of two ac[hro]matic prisms, or wedges, applied between the obj[ect-] glass and eye-glass of an achromatic telescope, by mo[ving] of which wedges nearer to or farther from the obj[ect-] glass, the two images of an object produced by them [ap]peared to approach to, or recede from, each other, so [that] the focal length of the object-glass becomes a scale [for] measuring the angular distance of the two images. [The] rationale and use of this micrometer are explained in [the] Philos. Trans. vol. 67, pa. 799, &c. And a similar in[...]

tion by the Abbé Rochon, which was afterwards improved by the Abbé Boscovich, was also communicated to the Royal Society, and published in the same volume of the Transactions, pa. 789, &c.

Mr. Ramsden invented two other micrometers, which he has contrived for remedying the defects of the object-glass micrometer. One of these is a catoptric micrometer, which, besides the advantage it derives from the principle of reflection, of not being disturbed by the heterogeneity of light, avoids every defect of other instruments of this kind, and can have no aberration, nor any defect arising from the imperfection of materials, or of execution; as the great simplicity of its construction requires no additional mirrors or glasses, to those necessary for the telescope; and the separation of the image being effected by the inclination of the two specula, and not depending on the focus of a lens or mirror, any alteration in the eye of an observer cannot affect the angle measured. It has peculiar to itself the advantages of an adjustment, to make the images coincide in a direction perpendicular to that of their motion; and also of measuring the diameter of a planet on both sides of the zero; which will appear no inconsiderable advantage to observers who know how much easier it is to ascertain the contact of the external edges of two images, than their perfect coincidence.

The other micrometer invented and described by Mr. Ramsden, is adapted to the principle of refraction. It is applied to the erect eye-tube of a refracting telescope, and is placed in the conjugate focus of the first eye-glass, as the image is considerably magnified before it comes to the micrometer, any imperfection in its glass will be magnified only by the remaining eye-glasses, which in any telescope seldom exceeds 5 or 6 times; and besides, the size of the micrometer glass will not be the 100th part of the area which would be necessary, if it were placed at the object-glass; and yet the same extent of scale is preserved, and the images are uniformly bright in every part of the field of the telescope. See the description and construction of these two micrometers in the Philos. Trans. vol. 69, part 2, art. 27.

In vol. 72 of the Philos. Trans. for the year 1782, Dr. Herschel, after explaining the defects and imperfections of the parallel-wire micrometer, especially for measuring the apparent diameter of stars, and the distances between double and multiple stars, describes one, for these purposes, which he calls a lamp micrometer; one that is free from such defects, and has the advantage of a very enlarged scale. In speaking of the application of this instrument, he says, "It is well known to opticians and others, who have been in the habit of using optical instruments, that we can with one eye look into a microscope or telescope, and see an object much magnified, while the naked eye may see a scale upon which the magnified picture is thrown. In this manner I have generally determined the power of my telescopes; and any one who has acquired a facility of taking such observations, will very seldom mistake so much as one in 50 in determining the power of an instrument, and that degree of exactness is fully sufficient for the purpose.

"The Newtonian form is admirably adapted to the use of this micrometer; for the observer stands always erect, and looks in a horizontal direction, notwithstanding the telescope should be elevated to the zenith.—The scale of the micrometer at the convenient distance of 10 feet from the eye, with the power of 460, is above a quarter of an inch to a second; and by putting on my power of 932, I obtain a scale of more than half an inch to a second, without increasing the distance of the micrometer; whereas the most perfect of my former micrometers, with the same instrument, had a scale of less than the 2000th part of an inch to a second.

"The measures of this micrometer are not confined to double stars only, but may be applied to any other objects that require the utmost accuracy, such as the diameters of the planets or their satellites, the mountains of the moon, the diameters of the fixed stars, &c."

The micrometer has not only been applied to telescopes, and employed for astronomical purposes; but there have been various contrivances for adapting it to microscopical observations. Mr. Leeuwenhoek's method of estimating the size of small objects, was by comparing them with grains of sand, of which 100 in a line took up an inch. These grains he laid upon the same plate with his objects, and viewed them at the same time. Dr. Jurin's method was similar to this; for he found the diameter of a piece of fine silver wire, by wrapping it very close upon a pin, and observing how many rings made an inch: and he used this wire in the same manner as Leeuwenhoek used his sand. Dr. Hooke used to look upon the magnified object with one eye, while at the same time he viewed other objects, placed at the same distance, with the other eye. In this manner he was able, by the help of a ruler, divided into inches and small parts, and laid on the pedestal of the microscope, as it were to cast the magnified appearance of the object upon the ruler, and thus exactly to measure the diameter which it appeared to have through the glass; and this being compared with the diameter as it appeared to the naked eye, easily determined the degree in which it was magnified. A little practice, says Mr. Baker, will render this method exceedingly easy and pleasant.

Mr. Martin, in his Optics, recommends such a micrometer for a microscope as had been applied to telescopes; for he advises to draw a number of parallel lines on a piece of glass, with the fine point of a diamond, at the distance of one 40th of an inch from one another, and to place it in the focus of the eye-glass. By this method, Dr. Smith contrived to take the exact draught of objects viewed by a double microscope; for this purpose he advises the observer to get a lattice, made with small silver wires or squares, drawn upon a plain glass by the strokes of a diamond, and to put it into the place of the image formed by the object-glass. Then, by transferring the parts of the object, seen in the squares of the glass or lattice, upon similar corresponding squares drawn on paper, the picture may be exactly taken. Mr. Martin also introduced into compound microscopes another micrometer, consisting of a screw. See both these methods described in his Optics, pa. 277.

A very accurate division of a scale is performed by Mr. Coventry, of Southwark. The micrometers of his construction are parallel lines drawn on glass, ivory, or metal, from the 10th to the 10,000th part of an inch. These may be applied to microscopes, for measuring the size of minute objects, and the magnifying power of the glasses; and to telescopes, for measuring the size and distance of objects, and the magnifying power of the instrument. To measure the size of an object in a single microscope; lay it on a micrometer, whose lines are seen magnified in the same proportion with it, and they will give at one view the real size of the object. For measuring the magnifying power of the compound microscope, the best and readiest method is the following: On the stage in the focus of the object-glass, lay a micrometer, consisting of an inch divided into 100 equal parts; count how many divisions of the micrometer are taken into the field of view; then lay a two-foot rule parallel to the micrometer: fix one eye on the edge of the field of light, and the other eye on the end of the rule, which move, till the edge of the field of light and the end of the rule correspond; then the distance from the end of the rule to the middle of the stage, will be half the diameter of the field: ex. gr. If the distance be 10 inches, the whole diameter will be 20, and the number of the divisions of the micrometer contained in the diameter of the field, is the magnifying power of the microscope. For measuring the height and distance of objects by a micrometer in the telescope, see TELESCOPE.

Mr. Adams has applied a micrometer, that shows immediately the magnifying power of any telescope.

In the Philos. Trans. for 1791, a very simple scale micrometer for measuring small angles with the telescope is described by Mr. Cavallo. This micrometer consists of a thin and narrow slip of mother-of-pearl finely divided, and placed in the focus of the eye-glass of a telescope, just where the image of the object is formed; whether the telescope is a reflector or a refractor, provided the eye-glass be a convex lens. This substance Mr. Cavallo, after many trials, found much more convenient than either glass, ivory, horn, or wood, as it is a very steady substance, the divisions very easy marked upon it, and when made as thin as common writing-paper it has a very useful degree of transparency.

On this subject, see M. Azout's Tract, contained in Divers Ouvrages de Mathematique et de Phisique; par Messieurs de l'Academie Royal des Sciences; M. de la Hire's Astronomicæ Tabulæ; Mr. Townley, in the Philos. Trans. No. 21; Wolfius, in his Elem. Astron. § 508; Dr. Hooke, and many others, in the Philos. Trans. No. 29, &c; Hevelius, in the Acta Eruditorum, ann. 1708; Mr. Balshaser, in his Micrometria; also several volumes of the Paris Memoirs, &c.

MICROPHONES, instruments contrived to magnify small sounds, as microscopes do small objects.

MICROSCOPE, an optical instrument, composed of lenses or mirrors, by means of which small objects are made to appear larger than they do to the naked eye.

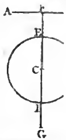
MICROSCOPES are distinguished into simple and compound, or single and double.

Simple, or *Single* MICROSCOPES, are such as consist of a single lens, or a single spherule. And a

Compound MICROSCOPE consists of several lenses properly combined.—As optics have been improved, other varieties have been contrived in this instrument: Hence reflecting microscopes, water microscopes, &c. It is not certainly known when, or by whom, microscopes were first invented; though it is probable they would soon follow on the use of telescopes, since a microscope is like a telescope inverted. We are informed by Huygens, that one Drebell, a Dutchman, had the first microscope, in the year 1621, and that he was reputed the inventor of it: though F. Fontana, a Neapolitan, in 1646, claims the invention to himself, and dates it from the year 1618. Be this as it may, it seems they were first used in Germany about 1621; and according to Peter Borelli, they were invented by Zacharias Jansen and his son, who presented th microscopes they had constructed to prince Maurice to Albert arch-duke of Austria. William Borelli, gives this account in a letter to his brother Peter, that when he was ambassador in England, in 1619, nelius Drebell showed him a microscope, which he was the same that the archduke had given him, and been made by Jansen himself. Borelli De vero scopii inventore, pa. 35, also on the Microscope. LENS.

Theory and Foundation of MICROSCOPES.

If an object be placed in the focus of the convex of a single microscope, and the eye be very near o other side, the object will appear distinct in an situation, and be magnified in the ratio of the foca tance of the lens, to the ordinary distance of distin sion, viz, about 8 inches. So, if the object AB be placed in the focus F, of a small glass sphere, and the eye behind it, as in the focus G, the object will appear distinct, and in an erect posture, its diameter being increased in the ratio of $\frac{3}{4}$ of the diameter EI to 8 inches. If, ex. gr. the diameter EI of the small sphere be $\frac{1}{10}$ of an inch; then $CE = \frac{1}{20}$, and $FE = \frac{1}{2} CE = \frac{1}{40}$, so that $CF = \frac{3}{40}$; then as $\frac{3}{40} : 8$, or as $3 : 320$, or as $1 : 106\frac{2}{3}$: : the natural size to the magnified ap ance; in which case, the object is magnified about times.



Hence the smaller the spherule or the lens is, so n the more is the object magnified. But then, so muc less part is comprehended at one view, and so muc less distinct is the appearance of the object.—Equal pearances of the same object, formed by different co nations, become obscure in proportion as the numb rays constituting each pencil decreases, that is, in pro tion to the smallness of the object-glass. Therefore, i diameter of the object-glass exceeds the diameter of pupil, as many times as the diameter of the appear exceeds the diameter of the object; the appearance be as clear and distinct as the object itself.

But the diameter of the object-glass cannot be so m increased, without increasing at the same time the distances of all the glasses, and consequently the leng the instrument: otherwise the rays would fall too liquely on the eye-glass, and the appearance become fused and irregular.

There are several kinds of single microscopes; of w the following is the most simple. AB (plate 22, fig is a small tube, to one end of which, BC, it fitted a p glass; and to this any object, as a gnat, the wing of an sect, or the like, is applied; to the other end AD, proper distance from the object, is applied a lens, con on both sides, of about an inch in diameter: the p glass is turned to the sun, or the light of a candle, and object is seen magnified. And if the tube be made draw out, lenses or segments of different spheres may used.

Again, a lens, convex on both sides, is inclosed in a AC (fig. 2), and held there by the screw H. Through stem or pedestal CD passes a long screw EF, carryi stile or needle FG. In E is a small tube; on which, on the point G, the various objects are to be dispo Thus, lenses of various spheres may be applied.

A good simple instrument of this kind is Mr. Wilson's pocket microscope, which has 9 different magnifying glasses, 8 of which may be used with two different instruments, for the better applying them to various objects. One of these instruments is represented at AABB (fig. 3), which is made either of brass or ivory. There are three thin brass plates at E, and a spiral spring H of steel wire within it: to one of the thin plates of brass is fixed a piece of leather F, with a small furrow G, both in the leather, and brass to which it is fixed: in one end of this instrument there is a long screw D, with a convex glass C, placed at the end it; at the other end of the instrument there is a hollow screw *oo*, in which any of the magnifying glasses, M, are screwed, when they are to be made use of. The 9 different magnifying glasses are all set in ivory, 8 of which are set in the manner expressed at M. The greatest magnifier is marked upon the ivory, in which it is set, number 1, the next number 2, and so on to number 8; the 9th glass is not marked, but is set in the manner of a little barrel box of ivory, as at *b*. At *ee* is a flat piece of ivory, of which there are 8 belonging to this sort of microscopes (though any one who has a mind to keep a register of objects may have as many of them as he pleases); in each of them there are 3 holes *fff*, in which 3 or more objects are placed between two thin glasses, or talcs, when they are to be used with the greater magnifiers.

The use of this instrument AABB is as follows: A handle W, from fig. 4, being screwed upon the button S, take one of the flat pieces of ivory or sliders *ee*, and slide it between the two thin plates of brass at E, through the body of the microscope, so that the object to be viewed be just in the middle; observing to put that side of the plate *ee*, where the brass rings are, farthest from the end AA: then screw into the hollow screw, *oo*, the 3d, 4th, 5th, 6th, or 7th magnifying glass M; which being done, put the end AA close to your eye, and while looking at the object through the magnifying glass, screw in or out the long screw D, and this moving round upon the leather F, held tight to it by the spiral wire H, will bring the object to the true distance; which may be known by seeing it clearly and distinctly.

Thus may be viewed all transparent objects, dusts, liquids, crystals of salts, small insects, such as fleas, mites, &c. If they be insects that will creep away, or such objects as are to be kept, they may be placed between the two register glasses *ff*. For, by taking out the ring that keeps in the glasses *ff*, where the object lies, they will fall out of themselves; so the object may be laid between the two hollow sides of them, and the ring put in again as before; but if the objects be dusts or liquids, a small drop of the liquid, or a little of the dust laid on the outside of the glass *ff*, and applied as before, will be seen very easily.

As to the 1st, 2d, and 3d magnifying glasses, being marked with a + upon the ivory in which they are set, they are only to be used with those plates or sliders that are also marked with a +, in which the objects are placed between two thin talcs; because the thickness of the glasses in the other plates or sliders, hinders the object from approaching to the true distance from these greater magnifiers. But the manner of using them is the same with the former.

For viewing the circulation of the blood at the extremities of the arteries and veins, in the transparent parts of fishes' tails, &c, there are two glass tubes, a larger and a smaller, as expressed at *gg*, into which the animal is put. When these tubes are to be used, turn the end screw D in the body of the microscrope, until the tube *gg* can be easily received into that little cavity G of the brass plate fastened to the leather F under the other two thin plates of brass at E. When the tail of the fish lies flat on the glass tube, set it opposite to the magnifying glass, and bringing it to the proper distance by screwing in or out the end screw D, and you will then clearly perceive the circulation of the blood.

To view the blood circulating in the foot of a frog; choose such a frog as will just go into the tube; then with a little stick expand its hinder foot, which apply close to the side of the tube, observing that no part of the frog hinders the light from coming on its foot; and when it is brought to the proper distance, by means of the screw D, the rapid motion of the blood will be seen in its vessels, which are very numerous, in the transparent thin membrane or web between the toes. For this object, the 4th and 5th magnifiers will do very well; but the circulation may be seen in the tails of water-newts in the 6th and 7th glasses, because the globules of the blood of those newts are as large again as the globules of the blood of frogs or small fish, as has been remarked in No. 280 of the Philos. Trans. pa. 1184.

The circulation cannot so well be seen by the 1st, 2d, and 3d magnifiers, because the thickness of the glass tube, containing the fish, hinders the approach of the object to the focus of the magnifying glass. Fig. 4 is another instrument for this purpose.

In viewing objects, one ought to be careful not to hinder the light from falling upon them by the hat, hair, or any other thing, especially in looking at opaque objects; for nothing can be seen with the best of glasses, unless the object be at a due distance, with a sufficient light. The best lights for the plates or sliders, when the object lies between the two glasses, is a clear sky-light, or where the sun shines on something white, or the reflection of the light from a looking-glass. The light of a candle is also very proper for viewing small objects, though it be a little uneasy to those who are not practised in the use of microscopes.

To cast small Glass Spherules for MICROSCOPES.—There are several methods for this purpose. Hartsoeker first improved single microscopes by using small globules of glass, melted in the flame of a candle; by which he discovered the animalculæ in semine masculino, and thereby laid the foundation of a new system of generation. Wolfius describes the following method of making such globules: A small piece of very fine glass, sticking to the wet point of a steel needle, is to be applied to the extreme bluish part of the flame of a lamp, or rather of spirits of wine, which will not black it; being there melted, and run into a small round drop, it is to be removed from the flame, on which it instantly ceases to be fluid. Then folding a thin plate of brass, and making very small smooth perforations, so as not to leave any roughness on the surfaces, and also smoothing them over to prevent any glaring, fit the spherule between the plates against the apertures, and put the whole in a frame, with objects convenient for observation.

Mr. Adams gives another method, thus: Take a piece of fine window-glass, and rase it, with a diamond, into as many lengths as you think needful, not more than 1-8th of an inch in breadth; then holding one of those lengths between the fore-finger and thumb of each hand, over a very fine flame, till the glass begins to soften, draw it out till it be as fine as a hair, and break; then applying each of the ends into the purest part of the flame, you presently have two spheres, which may be made greater or less at pleasure: if they remain long in the flame, they will have spots; so that they must be drawn out immediately after they are turned round. Break the stem off as near the globule as possible; and, lodging the remainder of the stem between the plates, by drilling the hole exactly round, all the protuberances are buried between the plates; and the microscope performs to admiration.

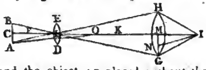
Mr. Butterfield gave another manner of making these globules, in No. 141 of Philos. Trans.

In any of these ways may the spherules be made much smaller than any lens; so that the best single microscopes, or such as magnify the most, are made of them. Leeuwenhoeck and Musschenbroek have succeeded very well in spherical microscopes, and their greatest magnifiers enlarged the diameter of an object about 160 times; Philos. Trans. vol. 7, pa. 129, and vol. 8, pa. 121. But the smallest globules, and consequently the highest magnifiers for microscopes, were made by F. de Torre of Naples, who, in 1765, sent four of them to the Royal Society. The largest of them was only two Paris points in diameter, and magnified a line 640 times; the second was the size of one Paris point, and magnified 1280 times; and the 3d no more than half a Paris point, or the 144th part of an inch in diameter, and magnified 2560 times. But since the focus of a glass globule is at the distance of one-4th of its diameter, and therefore that of the 3d globule of de Torre, above mentioned, only the 576th part of an inch distant from the object, it must be with the utmost difficulty that globules so minute as those can be employed to any purpose; and Mr. Baker, to whose examination they were referred, considers them as matters of curiosity rather than of real use. Philos. Trans. vol. 55, pa. 246, vol. 56, pa. 67.

Water MICROSCOPE. Mr. S. Gray, and, after him, Wolfius and others, have contrived water microscopes, consisting of spherules or lenses of water, instead of glass. But since the distance of the focus of a lens or sphere of water is greater than that in one of glass, the spheres of which they are segments being the same, consequently water microscopes magnify less than those of glass, and therefore are less esteemed. Mr. Gray first observed, that a small drop or spherule of water, held to the eye by candle-light or moon-light, without any other apparatus, magnified the animalcules contained in it, vastly more than any other microscope. The reason is, that the rays coming from the interior surface of the first hemisphere, are reflected so as to fall under the same angle on the surface of the hinder hemisphere, to which the eye is applied, as if they came from the focus of the spherule; whence they are propagated to the eye in the same manner as if the objects were placed without the spherule in its focus.

Hollow glass spheres of about half an inch diameter, filled with spirit of wine, are often used for microscopes; but they do not magnify near so much.

Theory of Compound or Double MICROSCOPES.—Suppose an object-glass ED, the segment of a very small



sphere, and the object AB placed without the focus F. Suppose an eye-glass GH, convex on both sides, and the segment of a sphere greater than that of DE, though not too great; and, the focus being at K, let it be so dis[…] behind the object, that CF : CL : : CL : CK. Lastly [sup]pose LK : LM : : LM : LI. If then O be the place [...] an object is seen distinct with the naked eye; th[e eye] in this case, being placed in I, will see the obje[ct] distinctly, in an inverted position, and magnified i[n the] compound ratio of MK × LC to LK × CO; as is p[roved] by the laws of dioptrics; that is, the image is large[r than] the object, and we are able to view it distinctly at [...] distance. For example—If the image be 20 times [larger] than the object, and by the help of the eye-glass w[e are] able to view it 5 times nearer than we could have [done] with the naked eye, it will, on both these accoun[ts, be] magnified 5 times 20, or 100 times.

Laws of Double MICROSCOPES.

1. The more an object is magnified by the micros[cope,] the less is its field, i. e. the less of it is taken in at one [view].

2. To the same eye-glass may be successively ap[plied] object-glasses of various spheres, so as that both the [entire] objects, but less magnified, and their several parts, [...] more magnified, may be viewed through the same m[icro]scope. In which case, on account of the different dist[ance] of the image, the tube in which the lenses are fitted sh[ould] be made to draw out.

3. Since it is proved, that the distance of the image from the object-glass DE, will be greater, if another [lens] concave on both sides, be placed before its focus; i[t fol]lows, that the object will be magnified the more, if [such] a lens be here placed between the object-glass DE, an[d the] eye-glass GH. Such a microscope is much commend[ed by] Conradi, who used an object-lens, convex on both s[ides,] whose radius was 2 digits, its aperture equal to a must[ard] seed; a lens, concave on both sides, from 12 to 16 di[gits;] and an eye-glass, convex on both sides, of 6 digits.

4. Since the image is projected to the greater dista[nce] the nearer another lens, of a segment of a larger spher[e, is] brought to the object-glass; a microscope may be c[om]posed of three lenses, which will magnify to a prodig[ious] extent.

5. From these considerations it follows, that the ob[ject] will be magnified the more, as the eye-glass is the segm[ent] of a smaller sphere; but the field of vision will be greater, as the same is a segment of a larger sph[ere.] Therefore if two eye-glasses, the one a segment of a la[rger] sphere, the other of a smaller one, be so combined, as [that] the object appearing very near through them, i.e. farther distant than the focus of the first, be yet distin[ct;] the object, at the same time, will be vastly magnified, [and] the field of vision much greater than if only one lens [were] used; and the object will be still more magnified, and [the] field enlarged, if both the object-glass and eye glass [be] double. But because an object appears dim when vie[wed] through so many glasses, part of the rays being reflec[ted] in passing through each, it is not adviseable greatly [to] multiply glasses; so that, among compound microsco[pes,] the best are those which consist of one object-glass [and] two eye-glasses.

Dr. Hooke, in the preface to his Micrography, sa[ys,] that in most of his observations he used a microscope [of] this kind, with a middle eye-glass of a considerable dia[me]ter, when he wanted to see much of the object at one vie[w,] and took it out when he would examine the small pa[rts] of an object more accurately; for the fewer refractio[ns] there are, the more light and clear the object appears.

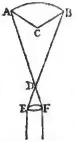
For a miscroscope of three lenses De Chales rec[...]

mends an object-glass of $\frac{1}{3}$ or $\frac{1}{4}$ of a digit; and the first eye-glass he makes 2 or $2\frac{1}{2}$ digits; and the distance between the object-glass and eye-glass about 20 lines. Conradi had an excellent miscroscope, whose object-glass was half a digit, and the two eye-glasses (which were placed very near) 4 digits; but it answered best when, instead of the object-glass, he used two glasses, convex on both sides, their sphere about a digit and a half, and at most 2, and their convexities touching each other within the space of half a line. Eustachio Divini, instead of an object-glass convex on both sides, used two plano-convex lenses, whose convexities touched. Grindeli did the same; only that the convexities did not quite touch. Zahnius made a binocular microscope, with which both eyes were used. But the most commodious double microscope, it is said, is that of our countryman Mr. Marshal; though some improvement was made in it by Mr. Culpepper and Mr. Scarlet. These are exhibited in figures 5 and 6.

It is observed, that compound microscopes sometimes exhibit a fallacious appearance, by representing convex objects concave, and vice versa. Philos. Trans. No. 476, pa. 387.

To fit microscopes, as well as telescopes, to short-sighted eyes, the object-glass and the eye-glass must be placed a little nearer together, so that the rays of each pencil may not emerge parallel, but may fall diverging upon the eye.

Reflecting MICROSCOPE, is that which magnifies by reflection, as the foregoing ones do by refraction. The inventor of this microscope was Sir Isaac Newton. The structure of such a microscope may be conceived thus: near the focus of a concave speculum AB, place a minute object C, that its image may be formed larger than itself in D; to the speculum join a lens, convex on both sides, EF, so as the image D may be in its focus. The eye will here see the image inverted, but distinct, and enlarged; consequently the object will be larger than if viewed through the lens alone.



Any telescope is changed into a microscope, by removing the object-glass to a greater distance from the eye-glass. And since the distance of the image is various, according to the distance of the object from the focus; and it is magnified the more, as its distance from the object-glass is greater; the same telescope may be successively changed into microscopes which magnify the object in different degrees. See some instruments of this sort described in Smith's Optics, Remarks, pa. 94.

Solar MICROSCOPE, called also the Camera Obscura Microscope, was invented by Mr. Lieberkuhn, in 1738 or 1739, and consists of a tube, a looking-glass, a convex lens, and a Wilson's microscope. The tube (fig. 7) is brass, near 2 inches in diameter, fixed in a circular collar of mahogany, with a groove on the outside of its periphery, denoted by 2, 3, and connected by a cat-gut to the pulley 4 on the upper part; which turning round at pleasure, by the pin 5 within, in a square frame, may be easily adjusted to a hole in the shutter of a window, by the screws I, I, so closely, that no light can enter the room but through the tube of the instrument. The mirror G is fastened to the frame by hinges, on the side that goes without the window: this glass, by means of a jointed brass wire, 6, 7, and the screw H 8, coming through the frame, may be moved either vertically or horizontally, to throw the sun's rays through the brass tube into the darkened room. The end of the brass tube without the shutter has a convex lens, 5, to collect the rays thrown on it by the glass G, and bring them to a focus in the other part, where D is a tube sliding in and out, to adjust the object to a due distance from the focus. And to the end O of another tube F, is screwed one of Wilson's simple pocket microscopes, containing the object to be magnified in a slider; and by tube F, sliding on the small end E, of the other tube D, it is brought to a true focal distance.

The solar microscope has been introduced into the small and portable camera obscura, as well as the large one: and if the image be received on a piece of half-ground glass, shaded from the light of the sun, it will be sufficiently visible. Mr. Lieberkuhn made considerable improvements in his solar microscope, particularly in adapting it to the viewing of opaque objects; and M Aepinus, Nov. Com. Petrop. vol. 9, pa. 326, has contrived, by throwing the light upon the foreside of any object, before it is transmitted through the object-lens, to represent all kinds of objects by it with equal advantage. In this improvement, the body of the common solar microscope is retained, and only an addition made of two brass plates, AB, AC (fig. 8), joined by a hinge, and held at a proper distance by a screw. A section of these plates, and of all the necessary parts of the instrument, may be seen in fig. 9, where *a c* represent rays of the sun converging from the illuminating lens, and falling upon the mirror *bd*, which is fixed to the nearer of the two brass plates. From this they are thrown upon the object at *cf*, and are thence transmitted through the object-lens at K, and a perforation in the farther plate, upon a screen, as usual. The use of the screen *n* is to vary the distance of the two plates, and thereby to adjust the mirror to the object with the greatest exactness. M. Euler also contrived a method of introducing vision by reflected light into this microscope.

The MICROSCOPE *for Opaque Objects* was also invented by M. Lieberkuhn, about the same time with the former, and it remedies the inconvenience of having the dark side of an object next the eye; for by means of a concave speculum of silver, highly polished, having a magnifying lens placed in its centre, the object is so strongly illuminated, that it may be examined with ease. A convenient apparatus of this kind, with 4 different speculums and magnifiers of different powers, was brought to perfection by Mr. Cuff. Philos. Trans. No. 458, § 9.

MICROSCOPIC *Objects*. All things too minute to be viewed distinctly by the naked eye, are proper objects for the microscope. Dr. Hooke has distinguished them into these three general kinds; viz, exceeding small bodies, exceeding small pores, or exceeding small motions. The small bodies may be seeds, insects, animalcules, sands, salts, &c: the pores may be the interstices between the solid parts of bodies, as in stones, minerals, shells, &c. or the mouths of minute vessels in vegetables, or the pores of the skin, bones, and other parts of animals; the small motions, may be the movements of the several parts or members of minute animals, or the motion of the fluids, contained either in animal or vegetable bodies. Under one or other of these three general heads, almost every thing about us affords matter of observation, and may conduce both to our amusement and instruction.

Great caution is to be used in forming a judgment on what is seen by the microscope, if the objects are extended or contracted by force or dryness. Nothing can be determined about them, without making the proper allowances; and different lights and positions will often show the same object as very different from itself. There is no advantage in any greater magnifier than such as is capable of showing the object in view distinctly; and the less the glass magnifies, the more pleasantly the object is always seen.—The colours of objects are very little to be depended on, as seen by the microscope; for their several component particles, being thus removed to great distances from one another, may give reflections very different from what they would, if seen by the naked eye.—The motions of living creatures too, or of the fluids contained in their bodies, are by no means to be hastily judged of from what we see by the microscope, without due consideration; for as the moving body, and the space in which it moves, are magnified, the motion must also be magnified; and therefore that rapidity with which the blood seems to pass through the vessels of small animals, must be judged of accordingly. Baker on the Microscope, pa. 52, 62, &c. See also an elegant work on this subject, published by that ingenious optician, the late Mr. George Adams.

The following directions are given for using the New Universal Pocket Microscope, made and sold by W. & S. Jones, opticians, Holborn, London. See fig. 4, pl. 33.

"This microscope is adapted to the viewing of all sorts of objects, whether transparent, or opake; and for insects, flowers, animalcules, and the infinite variety of the *minutiæ* of nature and art, will be found the most complete and portable, for the price, of any hitherto contrived.

"Place the square pillar of the microscope in the square socket at the foot D, and fasten it by the pin, as shown in the figure. Place also in the foot, the reflecting mirror C. There are three lenses at the top shown at A, which serve to magnify the objects. By using these lenses separately or combined, you make seven different powers. When transparent objects, such as are in the ivory sliders No. 4, are to be viewed, you place the sliders over the spring, at the underside of the stage B; then looking through the lens or magnifier, at A, at the same time reflect up the light, by moving the mirror C below, and move gently, upwards or downwards as may be necessary, the stage B on its square pillar, till you see the object illuminated and distinctly magnified; and in this manner for the other objects.

"For animalcules, you unscrew the brass box that is fitted at the stage B, containing two glasses, and leave the undermost glass upon the stage, to receive the fluids. If you wish to view thereon any moving insect, &c, it may be confined by screwing on the cover: of the two glasses, the concave is best for fluids. Should the objects be opake, such as seeds, &c; they are to be placed upon the black and white ivory round piece, No. 3, which is fitted also to the stage B. If the objects are of a dark colour, you place them contrastedly on the white side of the ivory. If they are of a white, or a light colour, upon the blackened side. Some objects will be more conveniently viewed, by sticking them on the point of No. 2; or between the nippers at the other end, which open by pressing the two little brass pins. This apparatus is also fitted to a small hole in the stage, made to receive the support of the wire.

"The brass forceps, No. 1, serve to take up any small object by, in order to place them on the stage for The instrument may be readily converted into a microscope, to view objects against the common ligh which, for some transparent ones, is better so. It i by only taking out the pillar from its foot in D, turi half round, and fixing it in again; the foot then be a useful handle, and the reflector C is laid aside. whole apparatus packs into a fish-skin case, 4¾ long, 2¾ inches broad, and 1¼ inches deep.

"For persons more curious and nice in these instrui there is contrived a useful adjusting screw to the sta presented at *e*. It is first moved up and down li other, to the focus nearly, and made fast by the screw. The utmost distinctness of the object is th tained, by gently turning the long fine-threaded scr the same time you are looking through the magnifi In this case, there may be also added an extraord deep magnifier, and a concave silver speculum, w magnifier to screw on at A, which will serve for vi the very small and opake objects in the completest ner, and render the instrument as comprehensive uses and powers, as those formerly sold under the of Wilson's Microscope."

MIDDLE *Latitude*, is half the sum of two given tudes; or the arithmetical mean, or the middle bet two parallels of latitude. Therefore, if the latitud of the same name, either both north or both south, the one number to the other, and divide the sum the quotient is the middle latitude, which is of the name with the two given latitudes. But if the lati be of different names, the one north and the other so subtract the less from the greater, and divide th mainder by 2, so shall the quotient be the middle titude, of the same name with the greater of the two.

	Ex. 1.		*Ex.* 2.
One lat.	35° 27′ N.		35° 27′ S.
the other	21 13 N.		21 13 N.
2)	56 40	2)	14 14
Mid. lat.	28 20 N.	Mid. lat.	7 7 S.

MIDDLE *Latitude Sailing*, is a method of resolving cases of globular sailing, by means of the middle latit on the principles of plain and parallel sailing joi This method is not quite accurate, yet often agrees p nearly with Mercator's sailing, and is founded on the lowing principle, viz, that the departure is account meridional distance in the middle latitude between latitude sailed from and the latitude arrived at.—' artifice seems to have been invented, on account of easy manner in which the several cases may be reso by the traverse table, and to serve where a table of m dional parts are wanting. It is sufficiently near the t either when the two parallels are near the equator, or far distant from each other, in any latitude. It is formed by these two rules:

1. As the cosine of the middle latitude :
   Is to radius : :
   So is the departure :
   To the difference of longitude .
2. As the cosine of the middle latitude :
   Is to the tangent of the course : :
   So is the difference of latitude :
   To the difference of longitude .

Ex. A ship sails from latitude 37° north, steering c stantly N. 33° 19′ east, for 8 days, when she was fo in latitude 51° 18′ north; required her difference of longitude.

	51°	18′		51°	18′
	37	00		37	00
2)	88	18	Diff. lat.	14	18 = 858 m.
As cos. mid. l.	44	09	-	0·14417	
To tang. cour.	33	19	-	9·81776	
So diff. lat.	858		-	2·93349	
To diff. long.	786		-	2·89542	

or 13° 6′ diff. of long. sought.

MIDDLE *Region*. See REGION.

MID HEAVEN, *Medium Cœli*, is that point of the ecliptic which culminates, or is highest, or is in the meridian at any time.

MIDSUMMER-*Day*, is held on the 24th of June, the same day as the nativity of St. John the Baptist.

MILE, a long measure, by which the English, Italians, and some other nations, use to express the distance between places: the same as the French use the word league. The mile is of different lengths in different countries. The geographical, or Italian mile, contains 1000 geometrical paces, mille passus, whence the term mile is derived. The English mile consists of 8 furlongs, each furlong of 40 poles, and each pole of 16¼ feet; so that the mile is = 8 furlongs = 320 poles = 1760 yards = 5280 feet.

The following table shows the length of the mile, or league, in the principal nations of Europe, expressed in geometrical paces, the pace being accounted equal to 4$\frac{4}{15}$ feet.

	Geomet. Paces.	Yards.
Mile of Russia	750	1100
of Italy	1000	1467
of England	1200	1760
of Scotland and Ireland	1500	2200
Old league of France	1500	2200
Small league, ibid.	2000	2933
Mean league of France	2500	3667
Great league, ibid.	3000	4400
Mile of Poland	3000	4400
of Spain	3428	5028
of Germany	4000	5867
of Sweden	5000	7333
of Denmark	5000	7333
of Hungary	6000	8800

MILITARY *Architecture*. The same with Fortification.

MILKY WAY, *Via Lactea*, or *Galaxy*, a broad track or path, encompassing the whole heavens, distinguishable by its white appearance, whence it obtains the name. It extends itself in some parts by a double path, but for the most part it is single. Its course lies through the constellations Cassiopeia, Cygnus, Aquila, Perseus, Andromeda, part of Ophiucus and Gemini, in the northern hemisphere; and in the southern, it takes in part of Scorpio, Sagittarius, Centaurus, the Argonavis, and the Ara. There are some traces of the same kind of light about the south pole, but they are small in comparison with this: these are called by some, luminous spaces and Magellanic clouds; but they seem to be of the same kind with the milky way.

The milky way has been ascribed to various causes. The ancients fabled, that it proceeded from a stream of milk, spilt from the breast of Juno, when she pushed away the infant Hercules, whom Jupiter laid to her breast to render him immortal. Some again, as Aristotle, &c, imagined that this path consisted only of a certain exhalation hanging in the air; while Metrodorus, and some Pythagoreans, thought the sun had once gone in this track, instead of the ecliptic; and consequently that its whiteness proceeds from the remains of his light. But it is now found, by the help of telescopes, that this track in the heavens consists of an immense multitude of stars, seemingly very close together, whose mingled light gives this appearance of whiteness; by Milton beautifully described as a path "powdered with stars." Dr. Herschel accounts it a stratum of nebulous matter.

MILL properly denotes a machine for grinding corn, &c; but in a more general signification, is applied to all machines whose action depends on a circular motion. Of these there are several kinds, according to the various methods of applying the moving power; as water-mills, wind-mills, horse-mills, hand-mills, &c, and even steam-mills, or such as are worked by the force of steam, as that noble structure that was erected near Blackfriars Bridge, called the Albion Mills, which was unfortunately destroyed by fire.

The water acts both by its impulse and weight in an overshot water-mill, but only by its impulse in an undershot one; but here the velocity is greater, because the water is suffered to descend to a greater depth before it strikes the wheel. Mr. Ferguson observes, that where there is but a small quantity of water, and a fall great enough for the wheel to lie under it, the bucket or overshot wheel is always used; but where there is a large body of water, with a little fall, the breast or float-board wheel must take place: and where there is a large supply of water, as a river, or large stream or brook, with very little fall, then the undershot wheel is the easiest, cheapest, and most simple structure.

Dr. Desaguliers, having had occasion to examine many undershot and overshot mills, generally found that a well made overshot mill ground as much corn, in the same time, as an undershot mill does with ten times as much water; supposing the fall of water at the overshot to be 20 feet, and at the undershot about 6 or 7 feet: and he generally observed that the wheel of the overshot mill was of 15 or 16 feet diameter, with a head of water of 4 or 5 feet, to drive the water into the buckets with some momentum.

In water-mills, some persons have given the preference to the undershot wheel, but most writers prefer the overshot one. M. Belidor greatly preferred the undershot to any other construction. He had even concluded, that water applied in this way would do more than 6 times the work of an overshot wheel; while Dr. Desaguliers, in overthrowing Belidor's position, determined that an overshot wheel would do 10 times the work of an undershot wheel, with an equal quantity of water. So that between these two celebrated authors, there is a difference of no less than 60 to 1. In consequence of such striking disagreement, Mr. Smeaton began the course of experiments mentioned below.

In the Philos. Trans. vol. 51, for the year 1759, we have a large paper with experiments on mills turned both by water and wind, by that ingenious and experienced engineer Mr. Smeaton. From those experiments it appears, pa. 129, that the effects obtained by the overshot wheel are generally 4 or 5 times as great as those with the undershot wheel, in the same time, with the same expense of water, descending from the same height above the bottom of the wheels; or that the former performs the same effect as the latter, in the same time, with an expense of only one-4th or one-5th of the water, from the same head or height. And this advantage seems to arise from the water lodging in the buckets, and so carrying the wheel about by their weight. But, in pa. 140, Mr. Smeaton reckons the effect of overshot only double to that of the undershot wheel. And hence he infers, in general, "that the higher the wheel is in proportion to the whole descent, the greater will be the effect; because it depends less upon the impulse of the head, and more upon the gravity of the water in the buckets. However, as every thing has its limits, so has this; for thus much is desirable, that the water should have somewhat greater velocity, than the circumference of the wheel, in coming upon it; otherwise the wheel will not only be retarded, by the buckets striking the water, but dashing a part of it over, so much of the power is lost." He is further of opinion, that the best velocity for an overshot wheel is when its circumference moves at the rate of about 3 feet in a second of time. See WIND-MILL.

Considerable differences have also arisen as to the mathematical theory of the force of water striking the floats of a wheel in motion. M. Parent, Maclaurin, Desaguliers, &c, have determined, by calculation, that a wheel works to the greatest effect, when its velocity is equal to one-third of the velocity of the water which strikes it; or that the greatest velocity that the wheel acquires, is one-third of that of the water. And this determination, which has been followed by all mathematicians, till very lately, necessarily results from a position which they assume, viz, that the force of the water against the wheel, is proportional to the square of its relative velocity, or of the difference between the absolute velocity of the water and that of the wheel. And this position is itself an inference which they make from the force of water striking a body at rest, being as the square of the velocity, because the force of each particle is as the velocity it strikes with, and the number of particles or the whole quantity that strikes is also as the same velocity. But when the water strikes a body in motion, the quantity of it that strikes is still as the absolute velocity of the water, though the force of each particle be only as the relative velocity, or that with which it strikes. Hence it follows, that the whole force or effect is in the compound ratio of the absolute and relative velocities of the water; and therefore is greater than the above-mentioned effect or force, in the ratio of the absolute to the relative velocity. The effect of this correction is, that the maximum velocity of the wheel becomes one half the velocity of the water, instead of one-third of it only: a determination which nearly agrees with the best experiments, as those of Mr. Smeaton.

This correction has been lately made by Mr. W. Waring, in the 3d volume of the Transactions of the American Philosophical Society, pa. 144. This ingenious writer says, 'Being lately requested to make some calculations relative to mills, particularly Dr. Barker's construction as improved by James Rumsey, I found more difficulty in the attempt than I at first expected. It appeared necessary to investigate new theorems for the purpose, as there are circumstances peculiar to this construction, which are not noticed, I believe, by any author; and the theory of mills, as hitherto published, is very imperfect, which I conceive to be the reason it has been of so little use to practical mechanics.

'The first step, then, toward calculating the power of any water-mill (or wind-mill), or proportioning their parts and velocities to the greatest advantage, seems to be,

'*The Correction of an Essential Mistake adopted by Writers on the Theory of Mills.*

'This is attempted with all the deference due to eminent authors, whose ingenious labours have justly raised their reputation and advanced the sciences; but when any wrong principles are successively published by a series of such pens, they are the more implicitly received, and more particularly claim a public rectification; which must be pleasing, even to these candid writers themselves.'

A very ingenious writer in England, 'in his masterly treatise on the rectilinear motion and rotation of bodies published so lately as 1784, continues this oversight, with its pernicious consequences, through his propositions and corollaries (pa. 275 to 284), although he knew the theory was suspected: for he observes (pa. 382) "Mr Smeaton in his paper on mechanic power (published in the Philosophical Transactions for the year 1776) allows that the theory usually given will not correspond with matter of fact, when compared with the motion of machines; and seems to attribute this disagreement, rather to deficiency in the theory, than to the obstacles which have prevented the application of it to the complicated motion of engines, &c. In order to satisfy himself concerning the reason of this disagreement, he constructed a set of experiments, which, from the known abilities and ingenuity of the author, certainly deserve great consideration and attention from every one who is interested in these inquiries." And notwithstanding the same learned author says, "The evidence upon which the theory rests is scarcely less than mathematical;" I am sorry to find in the present state of the sciences, one of his abilities concluding (pa. 380), "It is not probable that the theory of motion, however incontestable its principles may be, can afford much assistance to the practical mechanic," although indeed his theory, compared with the above-cited experiments, might suggest such an inference. But to come to the point, I would just premise these

'*Definitions.*

'If a stream of water impinge against a wheel in motion there are three different velocities to be considered, appertaining thereto, viz,

'First, the absolute velocity of the water;

'Second, the absolute velocity of the wheel;

'Third, the relative velocity of the water to that of the wheel, i. e. the difference of the absolute velocities, or the velocity with which the water overtakes or strikes the wheel.

'Now the mistake consists in supposing the momentum or force of the water against the wheel, to be in the duplicate ratio of the relative velocity: Whereas,

'PROP. I.

'The force of an Invariable Stream, impingeing against a Mill-wheel in Motion, is in the Simple Direct Proportion of the Relative Velocity.

'For, if the relative velocity of a fluid against a single plane be varied, either by the motion of the plane, or of the fluid from a given aperture, or both, then the number of particles acting on the plane in a given time, and likewise the momentum of each particle, being respectively as the relative velocity, the force on both these accounts must be in the duplicate ratio of the relative velocity agreeably to the common theory, with respect to the single plane: but, the number of these planes, or parts of the wheel acted on in a given time, will be as the velocity of the wheel, or inversely as the relative velocity; therefore, the moving force of the wheel must be in the simple direct ratio of the relative velocity. Q. E. D.

'Or the proposition is manifest from this consideration; that, while the stream is invariable, whatever be the velocity of the wheel, the same number of particles or quantity of the fluid, must strike it somewhere or other in a given time; consequently the variation of force is *only* on account of the varied impingent velocity of the same body, occasioned by a change of motion in the wheel; that is, the momentum is as the relative velocity. Now, this true principle substituted for the erroneous one in use, will bring the theory to agree remarkably with the notable experiments of the ingenious Smeaton, before-mentioned, published in the Philosophical Transactions of the Royal Society of London for the year 1760, vol. 51, for which the honorary annual medal was adjudged by the society, and presented to the author by their president. An instance or two of the importance of this correction may be adduced as below.'

PROP. II.

'The velocity of a wheel, moved by the impact of a stream, must be half the velocity of the fluid, to produce the greatest possible effect.—For let

V = the velocity, m = the momentum of the fluid;

v = the velocity, p = the power of the wheel.

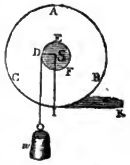
Then $V - v$ = the relative velocity, by def. 3d;

and as $V : V - v :: m : \frac{m}{V} \times (V - v) = p$ (prop. 1);

this multiplied by v, gives $pv = \frac{m}{V} \times (Vv - v^2)$ = a maximum; hence $Vv - v^2$ = a maximum, and its fluxion (v being the variable quantity) is $V\dot{v} - 2v\dot{v} = 0$; therefore $v = \frac{1}{2}V$, that is, the velocity of the wheel = half that of the fluid, at the place of impact, when the effect is a maximum. Q. E. D.—The usual theory gives $v = \frac{1}{3}V$; where the error is not less than one third of the true velocity of the wheel.

'This proposition is applicable to undershot-wheels, and corresponds with the accurate experiments before cited, as appears from the author's conclusion (Philos. Trans. for 1776, pa. 457), viz, "The velocity of the wheel, which according to M. Parent's determination, adopted by Desaguliers and Maclaurin, ought to be no more than one third of that of the water, varies at the maximum in the experiments of table 1, between one third and one half; but in all the cases there related, in which the most work is performed in proportion to the water expended, and which approach the nearest to the circumstances of great works when properly executed, the maximum lies much nearer one half than one third, one half seeming to be the true maximum, if nothing were lost by the resistance of the air, the scattering of the water carried up by the wheel, &c." Thus he fully shows the common theory to have been very defective; but, I believe, none have since pointed out wherein the deficiency lay, nor how to correct it; and now we see the agreement of the true theory with the result of his experiments.' For another problem.

PROP. III.



'Given, the momentum (m) and velocity (V) of the fluid at I, the place of impact; the radius (R = IS) of the wheel ABC; the radius (r = DS) of the small wheel DEF on the same axle or shaft; the weight (w) or resistance to be overcome at D, and the friction (f) or force necessary to move the wheel without the weight; required the velocity (v) of the wheel, &c.'

'Here we have $V : V - v :: m : m \times \frac{V - v}{V}$ = the acting force at I in the direction IK, as before (prop. 2). Now $R : r :: w : \frac{rw}{R}$ = the power at I necessary to counterpoise the weight w; hence $\frac{rw}{R} + f$ = the whole resistance opposed to the action of the fluid at I; which deducted from the moving force, leaves $m \times \frac{V - v}{V} - \frac{rw}{R} - f$ = the accelerating force of the machine; which, when the motion becomes uniform, will be evanescent or = 0; therefore $m \times \frac{V - v}{V} = \frac{rw}{R} + f$, which gives

$v = V \times (1 - \frac{rw}{mR} - \frac{f}{m})$ = the true velocity required; or, if we reject the friction, then $v = V \times (1 - \frac{rw}{mR})$ is the theorem for the velocity of the wheel. This, by the common theory, would be $v = V \times (1 - \sqrt{\frac{rw}{mR}})$, which is too little by $V\sqrt{\frac{rw}{mR}} - V\frac{rw}{mR}$. No wonder why we have hitherto derived so little advantage from the theory.'

'COROL. 1.—If the weight (w) or resistance be required, such as just to admit of that velocity which would produce the greatest effect; then, by substituting $\frac{1}{2}V$ for its equivalent v (by prop. 2), we have $\frac{1}{2}V = V \times (1 - \frac{rw}{mR} - \frac{f}{m})$; hence $w = \frac{\frac{1}{2}m - f}{r} \times R$; or, if $f = 0$, $w = \frac{mR}{2r}$; but theorists make this $\frac{4mR}{9r}$, where the error is $\frac{mR}{18r}$.'

'COROL. 2. We have also $r = \frac{\frac{1}{2}m - f}{w} \times R$; or, rejecting friction, $r = \frac{mR}{2w}$, when the greatest effect is produced, instead of $r = \frac{4mR}{9w}$, as has been supposed: this is an important theorem in the construction of mills.'

In the same volume of the American Transactions, pa. 185, is another ingenious paper, by the same author, on the power and machinery of Dr. Barker's mill, as improved by Mr. James Rumsey, with a description of it. This is a mill turned by the resisting force of a stream of water that issues from an orifice, the rotatory part, in which that orifice is, being impelled the contrary way by its reaction against the stream that issues from it.

Mr. Ferguson has given the following directions for constructing water-mills in the best manner; with a table of the several corresponding dimensions proper to a great variety of perpendicular falls of the water. When the float-boards of the water-wheel move with a 3d part (it should be $\frac{1}{2}$) of the velocity of the water that acts upon them, the water has the greatest power to turn the mill: and when the millstone makes about 60 turns in a minute, it is found to perform its work the best: for, when it makes but about 40 or 50, it grinds too slowly; and when it makes more than 70, it heats the meal too much, and cuts the bran so small that a great part of it mixes with the meal, and cannot be separated from it by sifting or boulting. Consequently the utmost perfection of mill-work lies in making the train so as that the millstone shall make about 60 turns in a minute when the water-wheel moves with a 3d part of the velocity of the water. To have it so, observe the following rules:

1. Measure the perpendicular height of the fall of water, in feet, above the middle of the aperture, where it is let out to act by impulse against the float-boards on the lowest side of the undershot wheel.

2. Multiply that height of the fall in feet by the constant number $64\frac{1}{3}$, and extract the square root of the product, which will be the velocity of the water at the bottom of the fall, or the number of feet the water moves per second.

3. Divide the velocity of the water by 3 (or 2); and the quotient will be the velocity of the floats of the wheel in feet per second.

4. Divide the circumference of the wheel in feet, by the velocity of its floats; and the quotient will be the number of seconds in one turn or revolution of the great water-wheel, on the axis of which is fixed the cog-wheel that turns the trundle.

5. Divide 60 by the number of seconds in one turn of the water-wheel or cog-wheel; and the quotient will be the number of turns of either of these wheels in a minute

6. Divide 60 (the number of turns the millstone ought to have in a minute) by the abovesaid number of turns: and the quotient will be the number of turns the millstone ought to have for one turn of the water or cog wheel. Then,

7. As the required number of turns of the millstone in a minute, is to the number of turns of the cog-wheel in a minute, so must the number of cogs in the wheel, be to the number of staves or rounds in the trundle on the axis of the millstone, in the nearest whole number tha can be found.

By these rules the following Table is calculated; i which, the diameter of the water-wheel is supposed 18 feet and consequently its circumference $56\frac{4}{7}$ feet, and the dia meter of the millstone is 5 feet.

The Mill-Wright's Table.

Perpendicular height of the fall of water.	Velocity of the water in feet per second.	Velocity of the wheel in feet per second.	Number of turns of the wheel in a minute.	Required number of turns of the millstone for each turn of the wheel.	Nearest number of cogs and staves for that purpose. Cogs.	Staves.	Number of turns of the millstone for one turn of the wheel by these cogs and staves.	Number of turns of the millstone in a minute by these cogs and staves.

For the theory, &c, of wind-mills, see WIND-*Mill*.

MILLION, the number of ten hundred thousand, or a thousand times a thousand.

MINE, in Fortification, &c, is a subterraneous canal or passage, dug under any place or work intended to be blown up by gunpowder. The passage of a mine leading to the powder is called the Gallery; and the extremity, or place where the powder is placed, is called the Chamber. The line drawn from the centre of the chamber perpendicular to the nearest surface, is called the Line of lea Resistance; and the pit or hole, made by the mine wh sprung, or blown up, is called the Excavation. T mines made by the besiegers in the attack of a place, a called simply Mines; and those made by the besiege Counter-mines.

The fire is conveyed to the mine by a pipe or ho made of coarse cloth, of about an inch and half in d meter, called Saucisson, extending from the powder in t chamber to the beginning or entrance of the gallery, to the end of which is fixed a match, that the miner who sets fire to it may have time to retire before it reaches the chamber.

It is found by experiments, that the figure of the excavation made by the explosion of the powder, is nearly a paraboloid, having its focus in the centre of the powder, and its axis the line of least resistance; its diameter being more or less according to the quantity of the powder, to the same axis, or line of least resistance. Thus, M. Belidor lodged 7 different quantities of powder in as many different mines, of the same depth, or line of least resistance, 10 feet; the charges and greatest diameters of the excavation, measured after the explosion, were as follow:

		Powder.		Diam.
1st	-	120lb	-	$22\frac{2}{3}$ feet
2d	-	160	-	26
3d	-	200	-	29
4th	-	240	-	$31\frac{3}{4}$
5th	-	280	-	$33\frac{1}{2}$
6th	-	320	-	36
7th	-	360	-	38

From which experiments it appears, that the excavation, or quantity of earth blown up, is in the same proportion with the quantity of powder; whence the charge of powder necessary to produce any other proposed effect, will be had by the rule of proportion.

MINE-*Dial*, is a box and needle, with a brass ring divided into 360 degrees, with several dials graduated upon it, commonly made for the use of miners.

MINERALOGY, is that branch of philosophy which treats of the physical and chemical properties of unorganized bodies; commonly called crude matter, or minerals; by which we are enabled to determine their distinctive characters, and their particular rank in the general system: and is thus distinguished from geology, which treats, more particularly, of the reciprocal position of the different species of minerals, and of the masses composed of two or more of these species.

MINUTE, is the 60th part of a degree, or of an hour. The minutes of a degree are marked with the acute accent, thus ′; the seconds by two, ″; the thirds by three, ‴. The minutes, seconds, thirds, &c, in time, are sometimes marked the same way; but, to avoid confusion, the better way is, by the initials of the words; as minutes^{m}, seconds^{s}, thirds^{t}, &c.

MINUTE, in Architecture, usually denotes the 60th part of a module, but sometimes only the 30th part.

MIRROR, a speculum, looking-glass, or any other polished body, the use of which is to form the images of distinct objects by reflexion of the rays of light. Mirrors are either plane, convex, or concave. The first sort reflects the rays of light in a direction exactly similar to that in which they fall upon it, and therefore represents bodies in their natural magnitude. But the convex ones make the rays diverge much more than before reflexion, and therefore greatly diminish the images of those objects which they exhibit: while the concave ones, by collecting the rays into a focus, not only magnify the objects they show, but will also burn very fiercely when exposed to the rays of the sun; and hence they are commonly known by the name of Burning Mirrors.

In ancient times, the mirrors were made of some kind of metal; and from a passage in the Mosaic writings we learn, that the mirrors used by the Jewish women, were made of brass; a practice doubtless learned from the Egyptians. Any kind of metal, when well polished, will reflect very powerfully; but of all others, silver reflects the most, but it is too expensive a material for common use. Gold is also very powerful; and all metals, or even wood, gilt and polished, will act with considerable effect as burning mirrors. Even polished ivory, or straw nicely plaited together, will form mirrors capable of burning, if on a large scale.

Since the invention of glass, and the application of quicksilver to it, have become generally known, it has been universally employed for those plane mirrors used as ornaments to houses; but in making reflecting telescopes they have been found much inferior to metallic ones. It does not appear however that the same superiority belongs to the metallic burning mirrors, considered merely as burning speculums; since the mirror with which Mr. Macquer melted platina, though only 22 inches diameter, and made of quicksilvered glass, produced much greater effects than M. Villette's metal speculum, which was of a much larger size. It is very probable, however, that M. Villette's mirror was not so well polished as it ought to have been; as the art of preparing the metal for taking the finest polish, has but lately been discovered, and published in the Philos. Transactions, by Dr. Mudge of Plymouth, and, after him, by Mr. Edwards, Dr. Herschel, &c.

Some of the more remarkable laws and phenomena of plane mirrors, are as follow:—1. A spectator will see his image of the same size, and erect, but reversed as to right and left, and as far beyond the speculum as he is before it. As he moves to or from the speculum, his image will, at the same time, move towards or from the speculum also on the other side. In like manner if, while the spectator is at rest, an object be in motion, its image behind the speculum will be seen to move at the same rate. Also when the spectator moves, the images of objects that are at rest will appear to approach or recede from him, after the same manner as when he moves towards real objects.

2. If several mirrors, or several fragments or pieces of mirrors, be all disposed in the same plane, they will only exhibit an object once.

3. If two plane mirrors, or speculums, meet in any angle, the eye, placed within that angle, will see the image of an object placed within the same, as often repeated as there may be perpendiculars drawn determining the places of the images, and terminated without the angle. Hence, as the more perpendiculars, terminated without the angle, may be drawn as the angle is more acute; the acuter the angle, the more numerous the images. Thus, Z. Traber found, at an angle of $\frac{1}{3}$d of a circle, the image was represented twice, at $\frac{1}{4}$th thrice, at $\frac{1}{6}$th five times, and at $\frac{1}{12}$th eleven times.

Further, if the mirrors be placed upright, and so contracted; or if you retire from them, or approach to them, till the images reflected by them coalesce, or run into one, they will appear monstrously distorted. Thus, if they be at an angle somewhat greater than a right one, the image of one's face will appear with only one eye; if the angle be less than a right one, you will see 3 eyes, 2 noses, 2 mouths, &c. At an angle still less, the body will have two heads. At an angle somewhat greater than a right one, at the distance of 4 feet, the body will be headless, &c. Again, if the mirrors be placed, the one parallel to the horizon, the other inclined to it, or declined from it, it is easy to perceive that the images will be still more romantic. Thus, one being declined from the horizon to an angle of 144 degrees, and the other inclined to it, a man sees himself standing with his head to another's feet.

Hence it appears how mirrors may be managed in gardens, &c, so as to convert the images of those near them into monsters of various kinds: and since glass mirrors will reflect the image of a lucid object twice or thrice, if a candle, &c, be placed in the angle between two mirrors, it will be multiplied a great number of times.

Laws of Convex Mirrors.

1. In a spherical convex mirror, the image is less than the object. And hence the use of such mirrors in the art of painting, where objects are to be represented less than the life.

2. In a convex mirror, the more remote the object, the less its image; also the smaller the mirror, the less the image.

3. In a convex mirror, the right hand is turned to the left, and the left to the right; and bodies perpendicular to the mirror appear inverted.

4. The image of a right line, perpendicular to the mirror, is a right line; but that of a right line oblique or parallel to the mirror, is convex.

5. Rays reflected from a convex mirror, diverge more than if reflected from a plane mirror; and the smaller the sphere, the more the rays diverge.

Laws of Concave Mirrors.

The effects of concave mirrors are, in general, the reverse of those of convex ones; rays being made to converge more, or diverge less than in plane mirrors; the image is magnified, and the more so as the sphere is smaller; &c, &c.

MITRE, in Architecture, is the workmen's term for an angle that is just 45 degrees, or half a right angle. And if the angle be the half of this, or a quarter of a right angle, they call it a half-mitre.

Mixt *Angle*, or *Figure*, is one contained by both right and curved lines.

Mixt *Number*, is one that is partly an integer, and partly a fraction; as $3\frac{1}{4}$.

Mixt *Ratio*, or *Proportion*, is when the sum of the antecedent and consequent is compared with the difference of the antecedent and consequent;

$$\text{As if}\begin{cases}4:3::12:9\\ a:b::c:d\end{cases}$$

$$\text{then}\begin{cases}7:1::21:3\\ a+b:a-b::c+d:c-d.\end{cases}$$

MOAT, in Fortification, a deep trench dug round a town or fortress, to be defended, on the outside of the wall, or rampart. The breadth and depth of a moat often depend on the nature of the soil; according as it is marshy, rocky, or the like. The brink of the moat next the rampart, is called the scarp; and the opposite side, the counterscarp.

Dry Moat, is one that is without water; on which account it ought to be deeper than one that has water, called a wet moat. A dry moat, or one that has a little water, has often a small ditch running all along the middle of its bottom, called a cuvette.

Flat-bottomed Moat, is that which has no sloping, its corners being somewhat rounded.

Lined Moat, is that whose scarp and counterscarp are cased with a wall of mason's work lying aslope.

MOBILE, *Primum*, in the Ancient Astronomy, was a 9th heaven, or sphere, conceived above those of the planets and fixed stars. It was supposed that this was the first mover, and carried all the lower spheres about with it; by its rapidity communicating to them a motion carrying them round in 24 hours. But the diurnal apparent revolution of the heavens is now better accounted for, by the rotation of the earth on its axis, without the assistance of any such primum mobile.

MOBILITY, an aptitude or facility to be moved.

The mobility of mercury is owing to the smallness and sphericity of its particles; and these also render its fixation so difficult. The hypothesis of the mobility of the earth is the most plausible, and is universally admitted by modern astronomers.—Pope Paul V. appointed commissioners to examine the opinion of Copernicus with regard to the mobility of the earth. The result of their inquiry was, a prohibition to assert, not that the mobility was possible, but that it was really true: that is, they allowed the mobility of the earth to be held as an hypothesis, which gives an easy and sensible solution of the phenomena of the heavenly motions; but forbade this doctrine to be maintained as a thesis, or real effective thing; because they conceived it contrary to Scripture.

MODILLIONS, small inverted consoles under the soffit or bottom of the drip, or of the corniche, seeming to support the projecture of the larmier, in the Ionic, Composite, and Corinthian orders.

MODULAR *Ratio*, a term invented by Mr. Cotes, to denote the ratio or number whose logarithm is what he calls the modulus. This ratio is the ratio

$$\text{of } 1+\frac{1}{1}+\frac{1}{2}+\frac{1}{2.3}+\frac{1}{2.3.4}+\frac{1}{2.3.4.5}\ \&c \text{ to } 1, \text{ or}$$

$$\text{of } 1 \text{ to } 1-\frac{1}{1}+\frac{1}{2}-\frac{1}{2.3}+\frac{1}{2.3.4}-\frac{1}{2.3.4.5}\ \&c;$$

that is, the ratio of 2·718281828459 &c to 1,

or the ratio of 1 to 0·367879441171 &c.

See Modulus, and Cotes's Logometria.

MODULE, or Little Measure, in Architecture, a certain measure, taken at pleasure, for regulating the proportions of columns, and the symmetry or distribution of the whole building. Architects usually choose the diameter, or the semidiameter, of the bottom of the column, for their module; which they subdivide into minutes; for estimating all the other parts of the building by.

MODULUS, of a system of logarithms, a term used by Mr. Cotes, to denote the log. of the modular ratio. All the logs. in any system, are proportional to this modulus, which in the hyperbolic or Napier's logs. is 1, and in the common or Briggs's logs. is 0·4342944819 &c. See Modular *Ratio*, and Cotes's Logometria.

MOINEAU, a flat bastion raised before a curtin when it is too long, and the bastions of the angles too remote to be able to defend each other. Sometimes the moineau is joined to the curtin, and sometimes it is divided from it by a moat. Here musquetry are placed to fire each way.

MOIVRE, Dr. See Demoivre.

MOLYNEUX (William), an excellent mathematician and astronomer, was born at Dublin in 1656. After the usual grammar education, which he had at home, he was entered of the college of that city. Here he distinguished himself by the probity of his manners, as well as by the strength of his genius; and having made a remarkable progress in academical learning, and particularly in the new philosophy, as it was then called, after four years spent in this university, he was sent over to London, where he was admitted into the Middle Temple in 1675. Here he spent three years, in the study of the laws of his country. But the bent of his genius lay strongly toward mathematical and philosophical studies; and even at the university he conceived a dislike to scholastic learning, and fell into the methods of lord Bacon.

Returning to Ireland in 1678, he shortly after married Lucy the daughter of sir William Domville, the king's attorney-general. Being master of an easy fortune, he continued to indulge himself in prosecuting such branches of natural and experimental philosophy as were most agreeable to his fancy; in which astronomy having the greatest share, he began, about 1681, a literary correspondence with Mr. Flamsteed, the astronomer royal, which was continued for several years. In 1683 he formed a design of erecting a Philosophical Society at Dublin, in imitation of the Royal Society at London; and, by the countenance and encouragement of Sir William Petty, who accepted the office of president, began a weekly meeting that year, when our author was appointed their first secretary.

Mr. Molyneux's reputation for learning recommended him, in 1684, to the notice and favour of the first great duke of Ormond, then lord-lieutenant of Ireland; by whose influence chiefly he was appointed that year, jointly with sir William Robinson, surveyor-general of the king's buildings and works, and chief engineer.

In 1685, he was chosen fellow of the Royal Society at London; and the same year he was sent by the government to view the most considerable fortresses in Flanders. Accordingly he travelled through that country and Holland, as also of Germany and France; and carrying with him letters of recommendation from Flamsteed to Cassini, he was introduced to him and others, the most eminent astronomers in the several places through which he passed. Soon after his return from abroad, he published at Dublin, in 1686, his Sciothericum Telescopium, containing a Description of the Structure and Use of a Telescopic Dial, invented by him: another edition of which was published at London in 1700.

In 1688 the Philosophical Society of Dublin was broken up and dispersed by the confusion of the times. Mr. Molyneux had distinguished himself as a member of it from the beginning, and presented several discourses upon curious subjects, some of which were transmitted to the Royal Society at London, and afterwards printed in the Philosophical Transactions. In 1689, among great numbers of other Protestants, he withdrew from the disturbances in Ireland, occasioned by the severities of Tyrconnel's government; and after a short stay at London, he fixed himself with his family at Chester. In this retirement, he employed himself in putting together the materials he had some time before prepared for his Dioptrics, in which he was much assisted by Mr. Flamsteed; and in August 1690, he went to London to put it to the press, where the sheets were revised by Dr. Halley, who, at our author's request, gave leave for printing, in the appendix, his celebrated Theorem for finding the Foci of Optic Glasses. Accordingly the book came out, 1692, in 4to, under the title of "Dioptrica Nova: a Treatise of Dioptrics, in two parts; wherein the various effects and appearances of spherical glasses, both convex and concave, single and combined, in telescopes and microscopes, together with their usefulness in many concerns of human life, are explained." He gave it the title of Dioptrica Nova, both because it was almost wholly new, very little being borrowed from other writers, and because it was the first book that appeared in English upon the subject. The work contains several of the most generally useful propositions for practice, demonstrated in a clear and easy manner, for which reason it was for many years used by the artificers: and the second part is very entertaining, especially in the history which he gives of the several optical instruments, and of the discoveries made by them.

As soon as the public tranquillity was settled in his native country, he returned home; and, on the convening of a new parliament in 1692, was chosen one of the representatives for the city of Dublin. In the next parliament, in 1695, he was chosen to represent the university there, and continued to do so to the end of his life; that learned body having lately conferred on him the degree of doctor of laws. He was also nominated by the lord-lieutenant one of the commissioners for the forfeited estates, to which employment was annexed a salary of 500*l*. a year; but considering it as an invidious office, he declined it.

In 1698, he published "The Case of Ireland stated, in regard to its being bound by Acts of Parliament made in England;" in which it is supposed he has delivered all, or most, that can be said upon this subject, with great clearness and strength of reasoning.

Among many learned persons with whom he maintained correspondence and friendship, Mr. Locke was in a particular manner dear to him, as appears from their letters. In the above-mentioned year, which was the last of our author's life, he made a journey to England, on purpose to pay a visit to that great man; and not long after his return to Ireland, he was seized with a fit of the stone, which terminated his existence.

Besides the three works already mentioned, viz, the Sciothericum Telescopium, the Dioptrica Nova, and the Case of Ireland stated; he published a great number of pieces in the Philosophical Transactions, which are contained in the volumes 14, 15, 16, 18, 19, 20, 21, 22, 23, 26, 29, several papers commonly in each volume.

MOLYNEUX (*Samuel*), son of the former, was born at Chester in July 1689; and educated with great care by his father, according to the plan laid down by Locke on that subject. When his father died, he was left to the management of his uncle, Dr. Thomas Molyneux, an excellent scholar and physician at Dublin, and also an intimate friend of Mr. Locke, who executed his trust so well, that Mr. Molyneux became afterwards a most polite and accomplished gentleman, and was made secretary to George the 3d when prince of Wales. Astronomy and optics being his favourite studies, as they had been his father's, he projected many schemes for the advancement of them, and was particularly employed in the years 1723, 1724, and 1725, in perfecting the method of making telescopes; one of which instruments, of his own making, he had presented to John the 5th, king of Portugal.

Being soon after appointed a commissioner of the admiralty, he became so engaged in public affairs, that he had not leisure to pursue those inquiries any further, as he intended. He therefore gave his papers to Dr. Robert Smith, professor of astronomy at Cambridge, whom he invited to make use of his house and apparatus of instruments, in order to finish what he had left imperfect. But Mr. Molyneux dying soon after, Dr. Smith lost the opportunity; he however supplied what was wanting from M. Huygens and others, and published the whole in his "Complete Treatise of Optics."

MOMENT, in Time, is sometimes taken for an extremely small part of duration; but, more properly, it is only an instant or termination or limit in time, like a point in geometry. Maclaurin's Fluxions, vol. 1, pa. 245.

MOMENTS, in the new Doctrine of Infinites, denote the indefinitely small parts of quantity; or they are the same with what are otherwise called infinitesimals, and differences, or increments and decrements; being the momentary increments or decrements of quantity considered as in a continual flux. Moments are the generative principles of magnitude: they have no determined magnitude of their own; but are only inceptive of magnitude. Hence, as it is the same thing, if, instead of these moments, the velocities of their increases and decreases be made use of, or the finite quantities that are proportional to such velocities; the method of proceeding which considers the motions, changes, or fluxions of quantities, is denominated, by Sir Isaac Newton, the method of fluxions.

Leibnitz, and most foreigners, considering these infinitely small parts, or infinitesimals, as the differences of two quantities; and thence endeavouring to find the differences of quantities, i. e. some moments, or quantities indefinitely small, which taken an infinite number of times shall equal given quantities; call these moments, differences; and the method of procedure, the differential calculus.

MOMENT, or *Momentum*, in Mechanics, is the same thing with Impetus, or the quantity of motion in a moving body. In comparing the motions of bodies, the ratio of their momenta is always compounded of the quantity of matter and the celerity of the moving body: so that the momentum of any such body, may be considered as the rectangle or product of the quantity of matter and the velocity of the motion. As, if b denote any body, or the quantity or mass of matter, and v the velocity of its motion; then bv will express, or be proportional to, its momentum m. Also if B be another body, and V its velocity; then its momentum M, is as BV. So that, in general, $M : m :: BV : bv$, i. e. the momenta are as the products of the mass and velocity. Hence, if the momenta M and m be equal, then shall the two products BV and bv be equal also; and consequently $B : b :: v : V$, or the bodies will be to each other in the inverse or reciprocal ratio of their velocities; that is, either body is so much the greater as its velocity is less. And this force of momentum is of a different kind from, and incomparably greater than, any mere dead weight, or pressure whatever.

The momentum also of any moving body, may be considered as the aggregate or sum of all the momenta of the parts of that body; and therefore when the magnitudes and number of particles are the same, and also moved with the same celerity, then will the momenta of the wholes be the same also.

MONDAY, the second day in the week.

MONADES. DIGITS, indivisible things.

MONNIER, (PETER CHARLES LE) the son of Peter le Monnier, professor of philosophy at Paris, was born at Paris, November 20, 1715, and died at Lizieux in Normandy, April 2, 1799, in the 84th year of his age, and then the oldest astronomer in Europe. His observations and memoirs, to a vast number, are chiefly contained in the memoirs of the Royal Academy of Sciences; besides which, he published the Histoire Celeste, 1741, in 4to. In this work is twice found, but only as a fixed star, Dr. Herschel's new planet. From his earliest years he devoted himself to astronomy; when a youth of 16 he made his first observations, viz. of the opposition of Saturn. At 20, he was nominated a member of the Royal Academy of Sciences. In 1735, he accompanied Maupertuis in the expedition to Lapland, to measure a degree of the meridian: and he was the first astronomer who had the satisfaction of measuring the diameter of the moon on the sun's disk. In 1750, he drew a meridian at the Royal Château at Bellevue, where the king often made observations. Le Monnier was naturally of a very irritable temper; as ardently as he loved his friends, as easily could he be offended; and his hatred was then implacable. Lalande, who had been his pupil, had the misfortune to incur his displeasure; and he never after could regain his favour. At the time of Le Monnier's death, he had amassed a vast quantity of observations, which he could never be prevailed on to publish, but concealed them in a place, which it was feared he had forgotten; so that it has been supposed they are lost to the world, unless the place should happen to be known to the celebrated mathematician Lagrange, who married one of his daughters in 1792.

MONOCEROS, the *Unicorn*, one of the new constellations of the northern hemisphere, or one of those which Hevelius has added to the 48 old asterisms, and formed out of the stellæ informes, or those which were not comprised within the outlines of any of the others. In Hevelius's catalogue, the Unicorn contains 19 stars, but in the Britannic catalogue 31.

MONOCHORD, a musical instrument with only one string, used by the ancients to try the variety and proportion of sounds. It was formed of a rule, divided and subdivided into several parts, on which there is a moveable string stretched over two bridges at the extremes of it. In the interval between these is a sliding or moveable bridge, by means of which, in applying it to the different divisions of the line, the sounds are found to bear the same proportion to each other, as the division of the line cut by the bridge. This instrument is also called the Harmonical Canon, or the Canonical Rule, because it serves to measure the degrees of gravity or acuteness. Ptolemy examines his harmonical intervals by the monochord. When the chord was divided into two equal parts, so that the parts were as 1 to 1, they called them Unisons; but if they were as 2 to 1, they called them Octaves or Diapasons; when they were as 3 to 2, they called them Diapentes, or Fifths; if they were as 4 to 3, they called them Diatessarons, or Fourths; if the parts were as 5 to 4, they called them Diton, or Major-third; but if they were as 6 to 5, they were called a Demi-diton, or Minor-third; and lastly, if the parts were as 24 to 25, a Demitone, or Dieze.

The monochord, being thus divided, was properly what they called a system, of which there were many kinds, according to the different divisions of the monochord.

MONOCHORD is also used for any musical instrument consisting of only one chord or string. Such is the trump-marine.

MONOTRIGLYPH, a term in Architecture, denoting the space of one triglyph between two pilasters, or two columns.

MONSOON, a regular or periodical wind, that blows one way for 6 months together, and the contrary way the other 6 months of the year. These prevail in several parts of the eastern and southern oceans.

MONTH, the 12th part of the year, and is so called from the moon, by whose motions it was formerly regulated; being properly the time in which the moon runs through the zodiac. The lunar month is either illuminative, periodical, or synodical.

Illuminative MONTH, is the interval between the first appearance of one new moon and that of the next following. As the moon appears sometimes sooner after one change than after another, the quantity of the illuminative month is not always the same. The Turks and Arabs reckon by this month.

Lunar Periodical MONTH, is the time in which the moon runs through the zodiac, or returns to the same point again; the quantity of which is 27 days 7hrs 43m. 8 sec.

Lunar Synodical MONTH, called also a Lunation, is the time between two conjunctions of the moon with the sun, or between two new moons; the quantity of which is 29 days 12 hours 44 m. 2 sec. 48 thirds. The ancient Romans used lunar months, and made them alternately of 29 and 30 days: they marked the days of each month by three terms, viz, Calends, Nones, and Ides.

Solar MONTH, is the time in which the sun runs through one entire sign of the ecliptic, the mean quantity of which is 30 days 10 hours 29 min. 5 sec. being the 12th part of 365 ds. 5 hrs. 49 min. the mean solar year.

Astronomical or *Natural* MONTH, is that measured by some exact interval corresponding to the motion of the sun or moon. Such are the lunar and solar months above-mentioned.

Civil or *Common* MONTH, is an interval of a certain number of whole days, approaching nearly to the quantity of some astronomical month. These may be either lunar or solar. The

Civil Lunar MONTH, consists alternately of 29 and 30 days. Thus will two civil months be equal to two astronomical ones, abating for the odd minutes; and so the new moon will be kept to the first day of such civil months for a long time together. This was the month in civil or common use among the Jews, Greeks, and Romans, till the time of Julius Cæsar. The

Civil Solar MONTH, consisted alternately of 30 and 31 days, excepting one month of the twelve, which consisted only of 29 days, but every 4th year of 30 days. And this form of civil months was introduced by Julius Cæsar. Under Augustus, the 6th month, till then from its place called sextilis, received the name Augustus, now August, in honour of that prince; and, to make the compliment still the greater, a day was added to it; which made it consist of 31 days, though till then it had only contained 30 days; to compensate for which, a day was taken from February, making it consist of 28 days, and 29 every 4th year. And such are the civil or calendar months now used through Europe.

MONTUCLA (JOHN STEPHEN), member of the National Institute, and of the Academy of Berlin, censor royal of mathematical books, was born at Lyons, the 5th of September 1725. His father was a banker, by whom he was intended for the same profession; but the science of calculations, to which he was early introduced, soon produced a discovery of the natural bent of his mind. In the Jesuits-college at Lyons he laid a good foundation in the ancient languages, as well as in the mathematical sciences, which enabled him afterwards easily to acquire a competent acquaintance with the Italian, the German, the Dutch, and the English, which he not only read, but also spoke very well.

At 16 years of age Montucla lost his father; and his grandmother, who had been left guardian of his education, died 4 years after. Having finished his studies at Lyons, he went to Toulouse to study the law, a branch of study deemed necessary in the liberal education of every person not destined for the profession of arms.

From hence he repaired to Paris, to enjoy in that capital all the benefits it afforded to the studious, in the lessons of the best masters, in the rich collections of the productions of nature and art, in the best libraries of books, and in the united societies of the literati, among whom he found friends for the rest of his life, and which fixed and determined his choice and pursuit of the mathematical and philosophical sciences, in which he afterwards distinguished himself in so eminent a degree. It was only in relaxing and unbending his mind, from such severe exercises, that he could sometimes occupy himself privately on subjects of less magnitude; such as when he in a manner made an entire new book of Ozanam's Mathematical Recreations, by the multitude of articles added, abridged, or substituted: on which occasion he had so closely concealed from every person the secret of his concern in that neat and improved edition, that the work was actually sent to him to examine and authorize in his capacity of public censor for mathematical books, an honorary office to which he had some time before been appointed. To the last edition of those Recreations however, he set the initials of his name,

Many other pieces were in the like anonymous manner composed by Montucla; among which may be here noticed an ingenious and learned History of Researches relating to the quadrature of the circle, published in 1754; a work very interesting, on account of the number of speculators who have gone astray after that seducing phantom, and of the curious properties which the researches have given rise to.

On occasion of introducing into France, in 1756, the practice of inoculation, which had been introduced into England in 1721, by lady Montague, on her return from Constantinople, Montucla made a translation from the English of the principal writings on that subject, which he added to the Memoire of la Condamine.

In the year 1758, came out Montucla's grand work, the History of Mathematics, in 2 large volumes in 4to: a work of profound reading and learning, and upon which, young as he was, he had spent a great many years of his life. This performance, of immense labour and erudition, published at 33 years of his age, justly procured to the author a most distinguished place in the learned world. This history, so truly admirable, whether we consider the extreme clearness and precision with which the subjects are treated, or the profound learning it exhibits, having been long out of print, the author's employment under the government, as first commissary of the king's buildings, for many years prevented him from fully yielding to the solicitations of his learned friends, to continue the work through the 18th century, in a new and enlarged edition. But the unfortunate loss of his fortune and employment, by the late revolution in France, left him but too much leisure for that purpose. The consequence, happy in this instance for the sciences, has been a new edition in 4 large volumes; in which the history is continued down to the end of the 18th century, and the former parts also very much enlarged and corrected.

In 1755, Montucla was elected an associated member of the Academy at Berlin. And in 1761 he was placed at Grenoble as secretary to the office of intendance, where he united in a happy marriage with Maria Françoise Romand.

The duke de Choiseul having ordered, in 1764, a colony to be formed at Cayenne, Montucla went out there as first secretary to the commission, to which appointment was joined also that of astronomer royal. The affairs of the colony not proving successful, after 15 months Montucla returned again to Grenoble, bringing with him many useful observations and specimens in botany and natural history, which proved beneficial both to the sciences and to the public at large. This voyage also furnished him with those curious observations on the shining of the sea in many places, and of various luminous insects, which are inserted near the end of the 4th volume of his Recreations.

Soon after his return, Montucla was appointed at Versailles to the honourable and profitable office of first commissioner of the royal and public buildings; an employment which he executed with great ability and usefulness during more than 25 years, till the overthrow of the monarchy put an end at once to this office, and the little fortune his regularity and œconomy had enabled him to save, throwing him again on the world, in his old age, naked and stript of every thing except his integrity, and the love and respect of his friends.

The modesty and integrity of Montucla were not less remarkable than his erudition. He was offered a place in the Academy of Sciences of Paris; which through delicacy he refused, as he felt he should not have leisure sufficient properly to attend to the duties of it. The portions of time which others would give to their pleasures, or amusements in their families, he always devoted to the details of the duties of his office, or to his studies. The translation from the English, of Carver's Travels in North America, was the sole monument of his pen, during that long interval. And even this was produced properly in the faithful discharge of the public duties with which he was charged. Being particularly intrusted by the government with the correspondence relating to the voyages which it ordered, he made it his duty and care to collect all the accounts he could find relating to such enterprises by other countries. With this view, at first only amusing his family with the reading of Carver's Travels, finding it entertaining and instructive, he completed and published the whole translation.

Montucla was named a member of the National Institute from the time of its commencement. And the government of 1795 employed him in examining and analysing the treatises deposited in the national archives. He was named professor of mathematics of the central school at Paris; but the bad state of his health would not permit him to accept it; and the department honoured him with a place in the jury of central instruction. But a place in the office for the national lottery was the only resource for his family during two years; a pension of 2400 francs (100*l.*) given him by the minister Neufchateau on the death of Saussure, and which he enjoyed only four months before his decease, which happened the 18th of December 1799. It was chiefly occasioned, as it often happens to literary and sedentary men, by a retention of urine: leaving a widow, as also a daughter, married in 1783, and a son employed in the office of the minister for the interior.

Montucla was one of the many considerable mathematicians of the 18th century; being well acquainted with all the branches and improvements in those abstruse sciences. His taste however, always chaste and clear, led him to prefer the pure and luminous methods of the ancient mathematicians, and to blame, in the French and the Germans, the great neglect of the same principles, which they showed on all occasions by their preference of the more modern analysis.

In the qualities of his heart too Montucla was truly estimable: remarkably modest in his manner and deportment; benevolent far beyond the means of his small fortune: of a very respectable personal appearance; he spok with ease and precision, but unassuming and with simplicity; related anecdotes and stories in a pleasant and play ful manner; and breathing, in all his conduct and depor ment the sweetness of virtue, and the delicacy of a fin taste.

MOON, *Luna*, ☾, one of the heavenly bodies, bein a satellite, or secondary planet to the earth; consider as a primary planet, about which she revolves in an ellipt orbit, or rather the earth and moon revolve about a com mon centre of gravity, which is as much nearer to th earth's centre than to the moon's, as the mass of the fo mer exceeds that of the latter.

The mean time of a revolution of the moon about t earth, from one new moon to another, when she overtak the sun again, is 29d. 12 h. 44 m. 2s. 48th.; but she mov once round her own orbit in 27 d. 7 h. 43 m. 8s. movi about 2290 miles every hour; and turns once round h axis exactly in the time that she goes round the ear which is the reason that she shows always the same s towards us; and that her day and night taken togetl are just as long as our lunar month.

The mean distance of the moon from the earth is radii, or 30 diameters, of the earth; which is ab 237,500 miles. The mean excentricity of her orbi $\frac{55}{1000}$ or $\frac{1}{18}$th nearly of her mean distance, amountin about 13,000 miles. Her diameter is to that of the ea as 20 to 73, or nearly as 3 to 11, or 1 to $3\frac{2}{3}$; and the fore it is equal to 2180 miles: her mean apparent meter is 31′ 16″$\frac{1}{2}$, that of the sun being 32′ 12″. surface of the moon is to the surface of the earth, to $13\frac{1}{3}$, or as 3 to 40; so that the earth reflects 13 ti as much light upon the moon, as she does upon the ea and her solid content to that of the earth, as 3 to 146 as 1 to $48\frac{2}{3}$. The density of the moon's body is to of the earth, as 5 to 4; and therefore her quantit matter to that of the earth, as 1 to 39 very nearly; force of gravity on her surface, is to that on the ea as 100 to 293. The moon has little or no differen seasons; because her axis is almost perpendicular to ecliptic.

Phenomena and Phases of the MOON. The moon b a dark, opaque, spherical body, only shining with light she receives from the sun, hence only that turned towards him, at any instant, can be illumin the opposite side remaining in its native darkness: a the face of the moon visible on our earth, is that p her body turned towards us; so, according to the va positions of the moon, with respect to the earth and we perceive different degrees of illumination; some a large and sometimes a less portion of the enligh surface being visible: And hence the moon appears times increasing, then waning; sometimes horned, half-round; sometimes gibbous, then full and r This may be easily illustrated by means of an ivory which being before a candle in various positions, will present a greater or less portion of its illuminated hemisphere to the view of the observer, according to its situation in moving it round the candle.

The same phases may be otherwise exhibited thus: Let S represent the sun, T the earth, and ABCD &c the moon's orbit. (Plate 19, fig. 3.) Now, when the moon is at A, in conjunction with the sun S, her dark side being entirely turned towards the earth, she will be invisible, as at *a*, and is then called the new moon. When she comes to her first octant at B, or has run through the 8th part of her orbit, a quarter of her enlightened hemisphere will be turned towards the earth, and she will then appear horned, as at *b*. When she has run through the quarter of her orbit, and arrived at C, she shows us the half of her enlightened hemisphere, as at *c*, and she is then said to be at the half. At D she is in her 2d octant, and by showing us more of her enlightened hemisphere than at C, she appears gibbous, as at *d*. At her opposition at E her whole enlightened side is turned towards the earth, when she appears round, as at *e*, and she is said to be full; having increased all the way round from A to E. On the other side she decreases again all the way from E to A: thus, in her 3d octant at F, part of her dark side being turned towards the earth, she again appears gibbous, as at *f*. At G she appears still farther decreased, showing again just one half of her illuminated side, as at *g*. But when she comes to her fourth octant, at H, she presents only a quarter of her enlightened hemisphere, and again appears horned, as at *h*. And at A, having now completed her course, she again disappears, or becomes a new moon again, as at first. The earth also presents exactly the same phases to a spectator in the moon, as she does to us, but only in a contrary order, the one being full when the other changes, &c.

The Motions of the MOON are most of them very irregular. The only equable motion she has, is her revolution on her own axis, in the space of a month, or time in which she moves round the earth; which is the reason that she always turns the same face towards us. This exposure of the same face is not however so uniform, but that she turns sometimes a little more of the one side, and sometimes of the other, called the moon's libration; and also shows sometimes a little more towards one pole and sometimes towards the other, by a motion like a kind of wavering, or vacillation. The former of these motions happens from this circumstance: the moon's rotation on her axis is equable or uniform; while her motion in her orbit is unequal, being quickest when the moon is in her perigee, and slowest when in the apogee, like all other planetary motions; whence it happens that sometimes more of one side is turned to the earth, and sometimes of the other. And the other irregularity arises from this: that the axis of the moon is not perpendicular, but a little inclined to the plane of her orbit: and as this axis maintains its parallelism, in the moon's motion round the earth; it must necessarily change its situation, in respect to an observer on the earth; whence it happens that sometimes the one, and sometimes the other pole of the moon, becomes visible.

The very orbit of the moon is changeable, and does not always preserve the same figure: for though her orbit be elliptical, or nearly so, having the earth in one focus, the excentricity of the ellipse is varied, being sometimes increased, and sometimes diminished; viz, being greatest when the line of the apses coincides with that of the syzygies, and least when these lines are at right angles to each other. Nor is the apogee of the moon without an irregularity; being found to move forward, when it coincides with the line of the syzygies; and backward, when it cuts that line at right angles. Neither is this progress or regress uniform; for in the conjunction or opposition, it goes briskly forward; and in the quadratures, it either moves slowly forward, stands still, or goes backward.—The motion of the nodes is also variable; being quicker and slower in different positions.

The Physical Cause of the MOON'S *Motion*, about the earth, is the same as that of all the primary planets about the sun, and of the satellites about their primaries, viz, the mutual attraction between the earth and moon. As for the particular irregularities in the moon's motion, to which the earth and other planets are not subject, they arise from the sun, which acts on, and disturbs her in her ordinary course through her orbit; and are all mechanically deducible from the same great law by which her general motion is directed, viz, the law of gravitation and attraction. The other secondary planets which attend on Jupiter, Saturn, &c, are also subject to the like irregularities with the moon; as they are exposed to the same perturbating or disturbing force of the sun; but their distance secures them from being so greatly affected as the moon is, and also from being so well observed by us.

For a familar idea of this matter, it must first be considered, that if the sun acted equally on the earth and moon, and always in parallel lines, this action would serve only to restrain them in their annual motions round the sun, and no way affect their actions on each other, or their motions about their common centre of gravity. But because the moon is nearer the sun, in one half of her orbit, than the earth is, and farther off in the other half of her orbit; and because the power of gravity is always less at a greater distance: it follows, that in one half of her orbit the moon is more attracted than the earth towards the sun, and less attracted than the earth in the other half: and hence irregularities necessarily arise in the motions of the moon; the excess of attraction in the first case, and the defect in the second, becoming a force that disturbs her motion: and besides, the action of the sun, on the earth and moon, is not directed in parallel lines, but in lines that meet in the centre of the sun; which makes the effect of the disturbing force still the more complex and embarrassing. And hence, as well as from the various situations of the moon, arise the numerous irregularities in her motions, and the equations, or corrections, employed in calculating her places, &c.

Newton, as well as others, has computed the quantities of these irregularities, from their causes. He finds that the force added to the gravity of the moon in her quadratures, is to the gravity with which she would revolve in a circle about the earth, at her present mean distance, if the sun had no effect on her, as 1 to $178\frac{29}{40}$: he finds that the force subducted from her gravity in the conjunctions and oppositions, is double of this quantity; and that the area described in a given time in the quarters, is to the area described in the same time in the conjunctions and oppositions, as 10973 to 11073: and he finds that, in such an orbit, her distance from the earth in her quarters, would be to her distance in the conjunctions and oppositions, as 70 to 69. On these irregularities, see Maclaurin's Account of Newton's Discoveries, book 4, chap. 4; as also most books of astronomy. Other particulars relating to the moon's motions, &c, have been stated as follow: The power of the moon's influence, as to the tides, is to that of the sun, as 4·4815 to 1, according to Sir I. Newton; but different according to others.

As to the figure of the moon, supposing her at first to have been a fluid, like the sea, Newton calculates, that the earth's attraction would raise the water there near 90 feet high, as the attraction of the moon raises our sea 12 feet: whence the figure of the moon must be a spheroid, whose greatest diameter extended, will pass through the centre of the earth; and will be longer than the other diameter, perpendicular to it, by 180 feet; and hence it comes to pass, that we always see the same face of the moon; for she cannot rest in any other position, but always endeavours to conform herself to this situation: Princip. lib. 3, prop. 38.

Newton estimates the mean apparent diameter of the sun at 32′ 12″; as the moon is 31′ 17″. The density of the moon he concludes is to that of the earth, as 9 to 5 nearly; and that the mass, or quantity of matter, in the moon, is to that of the earth, as 1 to 26 nearly. The plane of the moon's orbit is inclined to that of the ecliptic, and makes with it an angle of about 5 degrees: but this inclination varies, being greatest when she is in the quarters, and least when in her syzygies.

As to the inequality of the moon's motion, she moves swifter, and, by the radius drawn from her to the earth, describes a greater area in proportion to the time, also has an orbit less curved, and by that means comes nearer to the earth, in her syzygies or conjunctions, than in the quadratures, unless the motion of her excentricity prevents it: which excentricity is the greatest when the moon's apogee falls in the conjunction, but least when this falls in the quadratures; her motion is also swifter in the earth's aphelion, than in its perihelion. The apogee also goes forward swifter in the conjunction, and slower at the quadratures: but her nodes are at rest in the conjunctions, and recede swiftest of all in the quadratures. The moon also perpetually changes the figure of her orbit, or the species of the ellipse she moves in.

There are also some other inequalities in the motion of this planet, which it is very difficult to reduce to any certain rule; as the velocities or horary motions of the apogee and nodes, and their equations, with the difference between the greatest eccentricity in the conjunctions, and the least in the quadratures; and that inequality which is called the variation of the moon. All these increase and decrease annually, in a triplicate ratio of the apparent diameter of the sun: and this variation is increased and diminished in a duplicate ratio of the time between the quadratures; as is proved by Newton in many parts of his Principia. He also found that the apogees in the moon's syzygies, go forward in respect of the fixed stars, at the rate of 23′ each day; and backwards in the quadratures 16′$\frac{1}{3}$ per day: and therefore the mean annual motions he estimates at 40 degrees.

The gravity of the moon towards the earth, is increased by the action of the sun, when the moon is in the quadratures, and diminished in the syzygies: and, from the syzygies to the quadrature, the gravity of the moon towards the earth is continually increased, and she is continually retarded in her motion: but from the quadrature to the syzygy, the moon's motion is perpetually diminished, and the motion in her orbit is accelerated.

The moon is less distant from the earth at the syzygic and more at the quadratures. As radius is to $\frac{3}{2}$ of the si of double the moon's distance from the syzygy, so is t addition of gravity in the quadratures, to the force whi accelerates or retards the moon in her orbit. And radius is to the sum or difference of $\frac{1}{4}$ the radius and $\frac{3}{4}$ t cosine of double the distance of the moon from t syzygy, so is the addition of gravity in the quadratures, the decrease or increase of the gravity of the moon at th distance.

The apses of the moon go forward when she is in t syzygies, and backward in the quadratures. But, in a whe revolution of the moon, the progress exceeds the regre In a whole revolution, the apses go forward the fastest wh the line of the apses is in the nodes; and in the same ca they go back the slowest of all in the same revolutic When the line of the apses is in the quadratures, the aps are carried in consequentia, the least of all in the syzygi but they return the swiftest in the quadratures; and in tl case the regress exceeds the progress, in one entire revol tion of the moon.

The excentricity of the orbit undergoes various chang every revolution. It is the greatest of all when the line the apses is in the syzygies, and the least when that line in the quadratures.—Considering one entire revolution the moon, cæteris paribus, the nodes move in antecedent swiftest of all when she is in the syzygies; then slow and slower, till they are at rest, when she is in the quadr tures.—The line of nodes acquires successively all possit situations in respect of the sun; and every year it go twice through the syzygies, and twice through the quadi tures.—In one whole revolution of the moon, the nodes back very fast when they are in the quadratures; th slower till they come to rest, when the line of nodes is the syzygies.

The inclination of the plane of the orbit is changed l the same force with which the nodes are moved; bei increased as the moon recedes from the node, and minished as she approaches it. The inclination of t orbit is the least of all when the nodes are come to t syzygies. For in the motion of the nodes from the syz gies to the quadratures, and in one entire revolution of t moon, the force which increases the inclination, excee that which diminishes it; therefore the inclination is i creased; and it is the greatest of all when the nodes are the quadratures.

The moon's motion being considered in general: l gravity towards the earth is diminished on her coming n the sun, and the periodical time is the greatest; as al the distance of the moon, cæteris paribus, the great when the earth is in the perihelion. All the errors the moon's motion are something greater in the co junction than in the opposition. All the disturbi forces are inversely as the cube of the distance of the s from the earth; which when it remains the same, they a as the distance of the moon from the earth. Consideri all the disturbing forces together, the diminution of gravi prevails.

The figure of the MOON's *path*, about the earth, is, as h been said, nearly an ellipse; but her path, in moving, t gether with the earth about the sun, is made up of a seri or repetition of epicycloids, and is in every point conca towards the earth. See Maclaurin's Account of Newto Discov. pa. 336, 4to. Ferguson's Astron. pa. 129, &c and Rowe's Flux. pa. 225, edit. 2.

Astronomy of the Moon.

To determine the Periodical and Synodical Months; or the period of the moon's revolution about the earth, and the period between one opposition or conjunction and another. In the middle of a lunar eclipse, the moon is in opposition to the sun: compute therefore the time between two such eclipses, at some considerable distance of time from each other; and divide this by the number of lunations that have passed in the mean time; so shall the quotient be the quantity of the synodical month. Compute also the sun's mean motion during the time of this synodical month, which add to 360°. Then, as the sum is to 360°, so is the synodical to the periodical month.

For example, Copernicus observed two eclipses of the moon, the one at Rome on November 6, 1500, at 12 at night, and the other at Cracow on August 1, 1523, at 4 h. 25 min. the difference of meridians being 0 h. 29 min.: hence the quantity of the synodical month is thus determined:

2d Observ.	1523^y	237^d	4^h	25^m
1st Observ.	1500	310	0	29
Difference	22	292	3	56
Add intercalary days		5		
Exact interval	22	297	3	56

which divided by 282, the number of lunations in that time, gives the synodical month $29^d\ 12^h\ 41^m$.

From two other observations of eclipses, the one at Cracow, the other at Babylon, the same author determines more accurately the quantity of the synodical month to be $29^d\ 12^h\ 43^m$ &c; and from other observations, probably more accurate still, the same is fixed at $29^d\ 12^h\ 44^m$.

The sun's mean motion in that time $29°\ 6'\ 24''\ 18'''$, added to 360°, gives the moon's motion 389 6 24 18; Therefore the periodical month is $27^d\ 7^h\ 43^m\ 5^s$.

According to the observations of Kepler,

the mean synodical month is	29^d	12^h	44^m	3^s	2^{th},
and the mean periodical month	27	7	43	8	

Hence, 1st, the quantity of the periodical month being given, the moon's diurnal or horary motion, &c, may be found: and thus may tables of the mean motion of the moon be constructed.

2. If the mean diurnal motion of the sun be subtracted from that of the moon, the remainder will give the moon's diurnal motion from the sun: and thus may a table of this motion be constructed.

3. Since the moon is in the node at the time of a total eclipse, if the sun's place be found for that time, and 6 signs be added to the same, the sum will give the place of that node.

4. By comparing the ancient observations with the modern, it appears, that the nodes have a motion, and that they proceed in antecedentia, or backwards, from Taurus to Aries, from Aries to Pisces, &c. Therefore, if the diurnal motion of the nodes be added to the moon's diurnal motion, the sum will be the motion of the moon from the node; and thence by simple proportion may be found in what time the moon goes 360° from the dragon's head, or ascending node, or in what time she goes from, and returns to it; that is, the quantity of the dracontic month.

5. If the motion of the apogee be subtracted from the mean motion of the moon, the remainder will be the moon's mean motion from the apogee; and hence, by the rule of three, the quantity of the anomalistic month is determined.

Thus, according to Kepler's observations,

The mean synodical month is		29^d	12^h	44^m	$3^s\ 2^{th}$
The periodical month		27	7	43	8
The place of the apogee for the year 1700 Jan. 1, old style, was	11^s	$8°$	$57'$	$1''$	
The place of the ascending node	4	27	39	17	
Mean diurnal motion of the moon		13	10	35	
Diurnal motion of the apogee			6	41	
Diurnal motion of the nodes			3	11

Lastly, the excentricity is 4362, of such parts as the semi-diameter of the excentric is 100,000.

To find nearly the Moon's *Age or Change.*

To the epact add the number and day of the month; their sum, abating 30 if it be above that number, is the moon's age; and her age taken from 30, shows the day of the change.—The numbers of the months, or monthly epacts, are the moon's age at the beginning of each month, when the solar and lunar years begin together; and are thus:

0	2	1	2	3	4	5	6	8	8	10	10
Jan.	Feb.	Mar.	Ap.	Ma.	Jun.	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.

Ex. To find the moon's age, Oct. 14, 1813.

Here, the epact is	9
Number of the month	8
Day of the month	14
The sum is	31
Subtract or abate	30
Leaves moon's age	1
Taken from	30
Days till the change	29
Answering to Nov. 12	

To find nearly the Moon's *Southing*, or coming to the meridian. Take $\frac{4}{5}$ or $\frac{8}{10}$ of her age, for her southing nearly; after noon, if it be less than 12 hours; but if greater, the excess is the time after the foregoing midnight.

Ex. Oct. 23, 1814.

The moon's age is 10 days

$\frac{8}{10}$ of which is 8^h the sou. afternoon.

Mr. Ferguson, in his Select Exercises, pa. 135, &c, has given very easy tables and rules for finding the new and full moons near enough the truth for any common almanac. But the Nautical Almanac, which is now always published for several years before-hand, in a great measure supersedes the necessity of these and other such contrivances.

Of the Spots and Mountains, &c, in the Moon.

The face of the moon is greatly diversified with inequalities, and parts of different colours, some brighter and some darker than the other parts of her disc. When viewed through a telescope, her face is evidently diversified with hills and valleys: and the same is also shown by the edge or border of the moon appearing jagged, when so viewed, especially about the confines of the illuminated part when the moon is either horned or gibbous.

The astronomers, Florenti, Langreni, Hevelius, Grimaldi, Riccioli, Cassini, and Delahire, &c, have drawn the face of the moon as viewed through telescopes; noting all the more shining parts, and, for the better distinction, marking them with some proper name; some of these authors calling them after the names of philosophers, astronomers, and other eminent men; while others denominate them from the known names of the different countries, islands, and seas on the earth. The names adopted by Riccioli however are mostly followed, as the names of Hipparchus, Tycho, Copernicus, &c. Fig. 4, plate 19, is a rather exact representation of the full moon in her mean libration, with the numbers to the principal spots according to Riccioli, Cassini, Mayer, &c, which denote the names as in the following list of them: also the asterisk refers to one of the volcanoes observed by Herschel.

* Herschel's Volcano

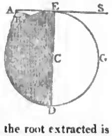
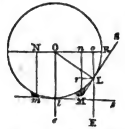
That the spots in the moon, which are taken for mountains and valleys, are really such, is evident from their shadows. For in all situations of the moon, the elevated parts are constantly found to cast a triangular shadow in a direction from the sun; and, on the contrary, the cavities are always dark on the side next the sun, and illuminated on the opposite one; which is exactly conformable to what we observe of hills and valleys on the earth. And as the tops of these mountains are considerably elevated above the other parts of the surface, they are often illuminated when they are at a considerable distance from the confines of the enlightened hemisphere, and by this means afford us a method of determining their heights.



Thus, let ED be the moon's diameter, ECD the boundary of light and darkness; and A the top of a hill in the dark part beginning to be illuminated; with a telescope take the proportion of AE to the diameter ED: then there are given the two sides AE, EC of a right-angled triangle ACE, the squares of which being added together give the square of the third side AC, and the root extracted is that side itself; from which subtracting the radius BC, leaves AB the height of the mountain. In this way, Riccioli observed the top of the hill called St. Catharine, on the 4th day after the new moon, to be illuminated when it was distant from the confines of the enlightened hemisphere about one 16th part of the moon's diameter; and thence found its height must be near 9 miles.

It is probable however that this determination is too much. Indeed, Galileo makes AE to be only one 20th of ED, and Hevelius makes it only one 26th of ED; the former of these would give $5\frac{1}{2}$ miles, and the latter only $3\frac{1}{4}$ miles, for AB, the height of the mountain: and probably it should be still less than either of these.

Accordingly, they are greatly reduced by the observations of Herschel, whose method of measuring them was given in the Philos. Trans. an. 1780, pa. 507, or my Abridg. v. 14, pa. 717; and which is as follows. This method is for any time whatever of the moon's age; whereas the method used by Hevelius, as above explained, will serve for the time of the quadrature only; in all other positions the projection of the hills must appear much shorter than it really is. Let SLM, or *slm*, be a line drawn from the sun to the mountain, touching the moon at L or *l*, and the mountain at M or *m*. Then, to an observer at E or *e*, the lines LM, *lm*, will not appear of the same length, though the mountains should be of an equal height; for LM will be projected into *on*, and *lm* into ON. But these are the quantities that are taken by the micrometer, when we observe a mountain to project from the line of illumination.



From the observed quantity *on*, when the moon is not in her quadrature, to find LM, we have the following analogy: the triangles LOO, LMr, are similar; therefore LO : LO : : Lr : LM; but LO is the radius of the moon, and Lr, or *on*, is the observed distance of the mountain's projection; and LO is the sine of the angle ROL = OLS, which we may take to be the distance of the sun from the moon, without any material error, and which therefore we may find at any given time from an ephemeris.

In this manner Dr. H. measured the height of many of the lunar prominences, and draws at last the following conclusions:—"From these observations I believe it is evident, that the height of the lunar mountains in general is greatly over-rated; and that, when we have excepted a few, the generality do not exceed half a mile in their perpendicular elevation." And this is confirmed by the measurement of several mountains, as may be seen in the place above quoted.

As the moon has on her surface mountains and valleys in common with the earth, some modern astronomers have discovered a still greater similarity, viz, that some of these are really volcanoes, emitting fire, as those on the earth do. An appearance of this kind was discovered some few years ago by Don Ulloa in an eclipse of the sun. It was a small bright spot like a star near the margin of the moon, and which he at that time supposed to be a hole or valley with the sun's light shining through it. Succeeding observations, however, have induced astronomers to attribute appearances of this kind to the eruption of volcanic fire; and Dr. Herschel has particularly observed several eruptions of the lunar volcanoes, the last of which he gives an account of in the Philos. Trans. for 1787, April 19, 10h. 6m. sidereal time, "I perceived," says he, "three volcanoes in different places of the dark part of the new moon. Two of them are either already nearly extinct, or otherwise in a state of going to break out; which perhaps may be decided next lunation. The third shows an actual eruption of fire or luminous matter: its light is much brighter than the nucleus of the comet which M. Mechain discovered at Paris the 10th of this month." The following night he found it burnt with greater violence; and by measurement he found that the shining or burning matter must be more than 3 miles in diameter; being of an irregular round figure, and very sharply defined on the edges. The other two volcanoes resembled large faint nebulæ, that are gradually much brighter in the middle; but no well-defined luminous spot was discovered in them. He adds, "the appearance of what I have called the actual fire, or eruption of a volcano, exactly resembled a small piece of burning charcoal when it is covered by a very thin coat of white ashes, which frequently adhere to it when it has been some time ignited; and it had a degree of brightness about as strong as that with which a coal would be seen to glow in faint day-light.

In a letter by M. Lalande, it is said that, the 13th inst. from 7 to 9 in the evening, Dom. Nouet, one of the astronomers of the Royal Observatory, perceived, in the unenlightened part of the moon, what Dr. Herschel has called a volcano, like a star of the sixth magnitude, or one of the cloudy ones, the brightness of which increased from time to time, as if by flashes. Other astronomers have perceived it, and M. de Villeneuve had seen it before, on the 22d of May, 1787. We cannot therefore doubt of the existence of this volcano in the moon. Dr. Herschel saw it the 4th of May, 1783, and particularly the 19th of April, 1787. In the eclipse of the 24th of June, 1778, M. d'Ulloa, a well-known Spanish astronomer, had seen on the dark disc of the moon, a bright point; and in the total eclipse of 1715, certain curious observers had perceived some flashes of light. There is no sensible atmosphere in the moon, it is true, and chemists may dispute about the name of volcanoes being given to such apparent eruption; but the name after all is of no consequence, and we must certainly subscribe to Dr. Herschel's opinion. This volcano is situated in the north-east part of the moon, about three minutes from the moon's border, towards the spot called Helicon, marked No. 12 in the figure of the moon in Lalande's astronomy. On the next day, March the 14th, Jupiter had been eclipsed by the moon. This rare and curious phenomena has been observed by all astronomers.

It has been disputed whether the moon has any atmosphere. The following arguments have been urged by those who deny it. 1. The moon, say they, constantly appears with the same brightness when our atmosphere is clear; which could not be the case if she were surrounded with an atmosphere like ours, so variable in its density, and so often obscured by clouds and vapours. 2. In an appulse of the moon to a star, when she comes so near it that a part of her atmosphere comes between our eye and the star, refraction would cause the latter to seem to change its place, so that the moon would appear to touch it later than by her own motion she would do. 3. Some philosophers are of opinion, that because there are no seas or lakes in the moon, there is therefore no atmosphere, as there is no water to be raised up in vapours.

But all these arguments have been answered by other astronomers in the following manner. It is denied that the moon appears always with the same brightness, even when our atmosphere appears equally clear. Hevelius relates, that he has several times found in skies perfectly clear, when even stars of the 6th and 7th magnitude were visible, that at the same altitude of the moon with the same elongation from the sun, and with the same telescope, the moon and her maculæ do not appear equally lucid, clear, and conspicuous at all times; but are much brighter and more distinct at some times than at others. And hence it is inferred that the cause of this phenomenon is neither in our air, in the tube, in the moon, nor in the spectator's eye; but must be looked for in something existing about the moon. An additional argument is drawn from the different appearances of the moon in total eclipses, which it is supposed are owing to the different constitutions of the lunar atmosphere.

To the 2d argument Dr. Long replies, that Newton has shown (Princip. prop. 37, cor. 5), that the weight of any body upon the moon is but a third part of what the weight of the same would be upon the earth: now the expansion of the air is reciprocally as the weight that compresses it; therefore the air surrounding the moon, being pressed together by a weight of one-third, or being attracted towards the centre of the moon by a force equal only to one-third of that which attracts our air towards the centre of the earth, it thence follows, that the lunar atmosphere is only one-third as dense as that of the earth, which is too little to produce any sensible refraction of the star's light. Other astronomers have contended, that such refraction was sometimes very apparent. M. Cassini says, he often observed that Saturn, Jupiter, and the fixed stars, had their circular figures changed into an elliptical one, when they approached either to the moon's dark or illuminated limb, though they own that, in other occultations, no such change could be observed. And, with regard to the fixed stars, it has been urged that, granting the moon to have an atmosphere of the same nature and quantity as ours, no such effect as a gradual diminution of light ought to take place; at least none that we could be capable of perceiving. At the height of 44 miles, our atmosphere is so rare as to be incapable of refracting the rays of light: this height is the 180th part of the earth's diameter; but since clouds are never observed higher than 4 miles, it appears that the vapourous or obscure part is only the 1980th part. The mean apparent diameter of the moon is 31′ 29″, or 1889″: therefore the obscure parts of her atmosphere, when viewed from the earth, must subtend an angle of less than one second; which space is passed over by the moon in less than two seconds of time. It can therefore hardly be expected that observation should generally determine whether the supposed obscuration takes place or not.

As to the 3d argument, it concludes nothing, because it is not known that there is no water in the moon; nor, though this could be proved, would it follow that the lunar atmosphere answers no other purpose than the raising of water into vapour. There is however a strong argument in favour of the existence of a lunar atmosphere, taken from the appearance of a luminous circle round the moon in the time of total solar eclipses; a circumstance that has been observed by many astronomers; especially in the total eclipse of the sun which happened May 1, 1706.

These are the arguments that have been advanced for and against the hypothesis of the existence of a lunar atmosphere; but this question seems to be at last settled, by the accurate and long continued observations of S. Piazzi, a celebrated astronomer, who has proved, as satisfactorily as the nature of the subject seems to allow, that the moon has really an atmosphere, though much less dense than ours, and the height of it scarcely exceeding some of the highest of the lunar mountains.

Of the Harvest MOON. It is remarkable that the moon, during the week in which she is at the full about the time of harvest, rises sooner after sun-setting, than she does in any other full-moon week in the year. By this means she affords an immediate supply of light after sun-set, which is very beneficial for the harvest and gathering in the fruits of the earth: and hence this full moon is distinguished from all the others in the year, by calling it the harvest-moon.

To conceive the reason of this phenomena, it may first be considered, that the moon is always opposite to the sun when she is full; that she is at the full in the signs Pisces and Aries in our harvest months, those being the signs opposite to Virgo and Libra, the signs occupied by the sun about the same season; and because those parts of the ecliptic rise in a shorter space of time than others, as may easily be shown and illustrated by the celestial globe: consequently, when the moon is about her full in harvest, she rises with less difference of time, or more immediately after sun-set, than when she is full at other seasons of the year.

In our winter, the moon is in Pisces and Aries about the time of her first quarter, when she rises about noon; but her rising is not then noticed, because the sun is above the horizon.—In spring, the moon is in Pisces and Aries about the time of her change; at which time, as she gives no light, and rises with the sun, her rising cannot be perceived.—In summer, the moon is in Pisces and Aries about the time of her last quarter; and then, as she is on the decrease, and rises not till midnight, her rising usually passes unobserved.—But in autumn, the moon is in Pisces and Aries at the time of her full, and rises soon after sunset for several evenings successively; which makes her regular rising very conspicuous at that time of the year.

And this would always be the case, if the moon's orbit lay in the plane of the ecliptic. But as her orbit makes an angle of 5° 18′ with the ecliptic, and crosses it only in the two opposite points called the nodes, her rising when in Pisces and Aries will sometimes not differ above 1 h. and 40 min. through the whole of 7 days; and at other times, in the same two signs she will differ 3 hours and a half in the time of her rising in a week, according to the different positions of the nodes with respect to these signs; which positions are constantly changing, because the nodes go backward through the whole ecliptic in 18 years and 225 days.

This revolution of the nodes will cause the harvest moons to go through a whole course of the most and least beneficial states, with respect to the harvest, every 19 years. The following table shows in what years the harvest moons are least beneficial as to the times of their rising, and in what years they are most beneficial, from the year 1790 to 1861; the column of years under the letter L, are those in which the harvest-moons are least beneficial, because they fall about the descending node; and those under the letter M are the most beneficial, because they fall about the ascending node.

Harvest Moons.

As to the Influence of the MOON, on the changes of the weather, and the constitution of the human body, it may be observed, that the vulgar doctrine concerning it is very ancient, and has also gained much credit among the learned, though perhaps without sufficient examination. The common opinion is, that the lunar influence is chiefly exerted about the time of the full and change, but more especially the latter; and it would seem that long experience has in some degree established the fact: hence, persons observed at those times to be a little deranged in their intellects, are called lunatics; and hence many persons anxiously look for the new moon to bring a change in the weather. The moon's influence on the sea, in producing tides, being agreed upon on all hands, it is argued that she must also produce similar changes in the atmosphere, but in a much higher degree; which changes and commotions there, must, it is inferred, have a considerable influence on the weather, and on the human body.

Besides the observations of the ancients, which tend to establish this doctrine, several among the modern philosophers have defended the same opinion, and that upon the strength of experience and observation; while others as strenuously deny the fact. The celebrated Dr. Mead was a believer in the influence of the sun and moon on the human body, and published a book on this subject, intitled, De Imperio Solis ac Lunæ in Corpore Humano. The existence of such influence was however opposed by bishop Horsley, in a learned paper on this subject, in the Philos. Trans. for the year 1775; where he gives a specimen of arranging tables of meteorological observations, so as to deduce from them facts, that may either confirm or refute this popular opinion; recommending it to the learned, to collect a large series of such observations, as no conclusions can be drawn from one or two only. On the other hand professor Toaldo, and some French philosophers, take the opposite side of the question; and, from the authority of a long series of observations, pronounce decidedly in favour of the Lunar Influence.

Acceleration of the MOON. See ACCELERATION.

MOORE (SIR JONAS), a very respectable mathematician, and surveyor-general of the ordnance, was born at Whitbee in Lancashire, about the year 1620. After enjoying the advantages of good school education, he bent his studies principally to the mathematics, to which he had always a strong inclination. In the expeditions of King Charles the 1st into the northern parts of England, our author was introduced to him, as a person studious and learned in those sciences; when the king expressed much approbation of him, and promised him encouragement; which indeed laid the foundation of his fortune. He was afterwards appointed mathematical master to the king's second son James, to instruct him in arithmetic, geography, the use of the globes, &c. During Cromwell's government it seems he followed the profession of a public teacher of mathematics; for I find him styled, in the title-page of some of his publications, "professor of the mathematics." After the return of Charles the 2d, he found great favour and promotion, becoming at length surveyor-general of the king's ordnance. He was also a great favourite both with the king and the duke of York, who often consulted him, and were advised by him on many occasions. And it must be owned that he often employed his interest with the court to the advancement of learning and the encouragement of merit. Thus, it was through his interest that Flamsteed-house was built in 1675, as a public observatory, recommending Mr. Flamsteed to be the king's astronomer, to make the observations there: and being surveyor-general of the ordnance himself, he made the salary of the astronomer-royal payable out of the office of ordnance, as it still continues. Being also a governor of Christ's-hospital, he prevailed on the king to found the mathematical school there, allowing a handsome salary for a master to instruct a certain number of the boys in mathematics and navigation, to qualify them for the sea-service. Here he soon found an opportunity of exerting his abilities in a manner somewhat answerable to his wishes, namely, that of serving the rising generation. And considering with himself the benefit the nation might receive from a mathematical school, if rightly conducted, he made it his utmost care to promote the improvement of it. But though the school was established, there still wanted a methodical institution from which the youths might receive such necessary helps as their studies required: a laborious work, from which his other great and assiduous employments might very well have exempted him, had not a predominant regard to a more general usefulness engaged him to devote all the leisure hours of his declining years to the improvement of so useful and important a seminary of learning.

Having thus engaged himself in the prosecution of this general design, he next sketched out the plan of a course or system of mathematics for the use of the school, and then drew up and published several parts of it himself, when death put an end to his labours, before the work was completed, about the middle of 1681, the year in which the work was published by his sons-in-law, Mr. Hanway and Mr. Potinger. Of this work, the Arithmetic, Practical Geometry, Trigonometry, and Cosmography, were written by Sir Jonas himself, and printed before his death. The Algebra, Navigation, and the books of Euclid were supplied by Mr. Perkins, at that time master of the mathematical school. And the Astronomy, or Doctrine of the Sphere, was written by Mr. Flamsteed, the astronomer-royal.

Further, as he was the king's constant counsellor in all matters of science, it was doubtless by his advice that the Royal Society also was founded in the year 1662.

The list of Sir Jonas's works, as far as I have seen them, is as follows:

1. The New System of Mathematics; above mentioned, in 2 vols 4to, 1681.

2. Arithmetic in two books, viz, Vulgar Arithmetic and Algebra. To which are added two Treatises, the one, A new Contemplation Geometrical, upon the Oval Figure called the Ellipsis; the other, The two first books of Mydorgius, his Conical Sections analized &c. 8vo, 1660.

3. A Mathematical Compendium; or Useful Practices in Arithmetic, Geometry, and Astronomy, Geography and Navigation, &c, &c. 12mo, 4th edition in 1705.

4. Modern Fortification, &c, 1673, in 8vo.

5. A General Treatise of Artillery: or, Great Ordnance. Written in Italian by Tomaso Moretii of Brescia. Translated into English, with notes thereupon, and some additions out of French for Sea-Gunners. By Sir Jonas Moore, Kt. 8vo, 1683.

MORELAND or MORLAND (Sir Samuel), an ingenious mechanist and philosopher. He was master of mechanics to king Charles the 2d, and he invented several useful machines; as, the speaking-trumpet, a fire-engine, and a capstan for heaving up anchors, &c. He published also a respectable book on Arithmetic, in 1674. Three papers of his are inserted in the Philos. Trans.; one on the speaking-trumpet above-mentioned; another on a scheme for raising water; and a third on a successful operation for the hydrops pectoris.

This author was the son of another Sir Samuel Morland, a great statesman, and under-secretary to the minister Thurlow. He was employed by Cromwell in several embassies, and had received the title of baronet for services rendered to King Charles the 1st.

In 1675, Sir S. got a patent for a certain powerful engine to raise water, which project was, in the preceding year, announced in the Philos. Trans. of the Royal Society. This machine, by the strength of 8 men, would force water, in a continual stream, from the river Thames, to the top of Windsor Castle, and 60 feet higher, at the rate of 60 barrels an hour; which experiment was repeated several times, in the year 1681, before the king, queen, and court; when his majesty presented to Sir S. a medal, with his effigy set round with diamonds, and constituted him his master of mechanics, &c. So that it seems it has not always been the practice to present to this office, without some view to public utility.—To Sir S. also it appears, is due the first account of the steam-engine; on which subject, he wrote a book, in which he not only showed the practicability of the plan, but went so far as to calculate the power of different cylinders. This book is now extant in manuscript, in the Harleian collection of MSS. in the British Museum, described in the improved Harleian catalogue, vol. iii, No. 5771, and it is also pointed out in the preface to that volume, sect. 32. The author dates his invention in 1682; consequently 17 years prior to Savery's patent. It was presented to the French king in 1683, at which time experiments were actually shown at St. Germain's. As Mr. S. held places under Charles the 2d, we must naturally conclude that he would not have gone over to France to offer his invention to Louis the 14th, had he not found it slighted at home. The project seems to have remained obscure in both countries till 1699, when Savery, who probably knew more of Morland's invention than he owned, obtained a patent; and in the very same year, M. Amontons proposed something similar to the French Academy, seemingly as his own.

MORTALITY. *Bills of Mortality*, are accounts or registers specifying the numbers born and buried, and sometimes married, in any town, parish, or district. These are of great use, not only in the doctrine of life annuities, but in showing the degrees of healthiness and prolificness, with the progress of population in the places where they are kept. It is therefore much to be wished that such accounts had always been correctly kept in every kingdom, and regularly published at the end of every year. We should then have had under inspection the comparative strength of every kingdom, as far as it depends on the number of inhabitants, and its increase or decrease at different periods.

Such accounts are rendered still more useful, when they include the ages of the dead, and the distempers of which they have died. In this case they convey some of the most important instructions, by furnishing the means of ascertaining the law which governs the waste of human life, the values of annuities dependent on the continuance of any lives, or any survivorships between them, and the favourableness or unfavourableness of different situations to the duration of life.

There are however but few registers of this kind; nor has this subject, though so interesting to mankind, ever engaged much attention till lately. Indeed, bills of mortality for the several parishes of the city of London have been kept from the year 1592, with little interruption; and a very ample account of them has been published down to the year 1759, by Dr. Birch, in a large 4to vol. which is perhaps the most complete work of the kind extant; containing besides the bills of mortality, with the diseases and casualties, several other valuable tracts on the subject of them, and on political arithmetic, by several other authors, as Capt. John Graunt, F. R. S.; Sir William Petty, F. R. S.; Corbyn Morris, Esq. F. R. S.; and J. P. Esq. F. R. S.; the whole forming a valuable repository of materials; and it would be well if a continuation were published, down to the present date, and so continued from time to time.

Bills, containing the ages of the dead, were long since published for the town of Breslaw in Silesia. It is well known what use has been made of these by Dr. Halley, and after him by Mr. Demoivre. A table of the probabilities of the duration of human life at every age, deduced from them by Dr. Halley, was published in the Philos. Trans. vol. 17, and has been inserted in this work under the article LIFE-*Annuities*; which is the first table of the kind that has been published. Since the publication of this table, similar bills have been established in many other places, in England, Germany, Switzerland, France, Holland, &c, but more particularly in Sweden; the results of some of which may be seen in the large comparative table of the duration of life, under our article LIFE-*Annuities*, as well as in the writings of Dr. Price, baron Maseres, Mr. Baily, &c.

MORTAR, or MORTAR-PIECE, a short piece of ordnance, thick and wide, proper for throwing bomb-shells, carcases, stones, grape-shot, &c. It is thought that the use of mortars is prior to that of cannon: for they were employed in the wars of Italy, to throw balls of red-hot iron, and stones, long before the invention of shells: and it is generally believed that the Germans were the first inventors. The practice of throwing red-hot balls out of mortars, was first practised at the siege of Stralsund in 1675, by the elector of Brandenburg; though some say, in 1653, at the siege of Bremen.

Mortars are made either of brass or iron, and it is usual to distinguish them by the diameter of the bore; as the 13 inch, the 10 inch, or the 8 inch mortar: there are some of a smaller sort, as Cochorns of 4·6 inches, and Royals of 5·8 inches in diameter. As to the larger sizes, as 18 inches, &c, they are now disused by the English, as well as most other European nations. For the circumstances relating to mortars, see Muller's Artillery.

Cochorn MORTAR, a small kind of one, invented by the celebrated engineer baron Coehorn, to throw small shells or grenades. These mortars have been sometimes fixed, to the number of a dozen, on a block of oak, at the elevation of 45°.

MOTION, or *Local* MOTION, is a continued and successive change of place. Borelli defines it, the successive passage of a body from one place to another, in a determinate time, by becoming successively contiguous to all the parts of the intermediate space. Or motion is that affection of matter by which it is transferred from one point of space to another.

In order that the doctrine of mechanics may be brought within the boundaries of mathematical investigation, it is necessary, not only that the quantities it proposes for discussion should be measurable, either in themselves or in their effects, but also that some general principles should be established, the truth of which should be incontrovertible, and to which the student may at all times appeal in the course of his researches. Such general principles were first distinctly proposed by Sir I. Newton, in his Principia, and they have since his time been received as mechanical axioms, or, as they are commonly called, Laws of Motion, which are as follows:

1. Every body continues in its state of rest or uniform motion in a right line, until a change is effected in it, by the agency of some external force.

2. Any change affected in the quiescence, or motion of a body, is in the direction of the force impressed, and is proportional to the quantity of it.

3. Action and reaction are equal and contrary; or the mutual actions of two bodies on each other, are always equal, and directed to contrary parts.

Continuation of MOTION, or the cause why a body, once in motion, continues to persevere in it, is a subject, that has been much controverted by many celebrated philosophers; we must, however, be content with knowing that it is one of the fundamental laws of nature, which is beyond the comprehension of the human mind; and by which, motion once begun, would be continued in infinitum, were it to meet with no interruption from external causes, such as the power of gravity, the resistance of mediums, &c, &c.

Communication of MOTION, or how a body in motion communicates the same to a body at rest, by coming in contact with it, is also a subject which has been as much controverted by philosophers as the former, and after all, is as little understood as the continuation of motion, the cause of gravity, and other speculative inquiries of a similar nature.

Motion, as we before observed, is the proper subject of mechanics, and these are the basis of all natural philosophy; and hence the denomination, Mechanical, or Experimental Philosophy.

In effect, all the phenomena of nature, all the changes that happen in the system of bodies, are owing to motion; and are directed according to the laws of it. Hence the modern philosophers have applied themselves with peculiar ardour to consider the doctrine of motion; to investigate the properties and laws of it; by observation and experiment, aided by the use of geometry. And to this is owing the great advantage of the modern philosophy over that of the ancients; who generally founded their systems of philosophy on some absurd hypothesis of their own invention; whereas the moderns, by deducing theirs from experiments, carefully and frequently repeated, are enabled to proceed from effects to their causes in a much more rational manner.

Motion is considered as of various kinds, viz, Absolute, Relative, Equable, Accelerated, Retarded, &c.

Absolute MOTION, is an absolute change of place, in any moving body, considered independently of any other motion, the celerity of which will therefore be measured by the quantity of absolute space which the moveable body has passed over. And

Relative MOTION, is the change of the relative place of a moving body, considered with respect to some other body also in motion, and the celerity of it is estimated by the quantity of relative space run through. This may be illustrated by considering two vessels, sailing either in the same, or in contrary directions, but with different velocities in the former case; both of which are in absolute motion with regard to the port whence they sailed, or any other fixed point, but in relative motion with respect to each other.

Among the ancients, there is nothing extant on motion, excepting some things in Archimedes's books De Æquiponderantibus, and in Aristotle's. We are indebted to Galileo for a great part of the doctrine of motion: he first discovered the general laws of it, and particularly of the descent of heavy bodies, both perpendicularly and on inclined planes; the laws of the motion of projectiles; the vibration of pendulums, and of stretched cords, with the theory of resistances, &c: things which the ancients had little notion of.

Torricelli considerably improved on the discoveries of his master, Galileo; and added many experiments concerning the force of percussion, and the equilibrium of fluids. Huygens extended the doctrine of pendulums; and both he and Borelli the effects of percussion. Lastly, Newton, Leibnitz, Varignon, Mariotte, &c, have brought the doctrine of motion still nearer to perfection.

The general laws of motion were first brought into a system, and analytically demonstrated together, by Dr. Wallis, Sir Christopher Wren, and M. Huygens, all much about the same time; the first in bodies not elastic, and the two latter in elastic bodies. Lastly, the whole doctrine of motion, including all the discoveries both of the ancients and moderns on that head, was given by Dr. Wallis in his Mechanica, sive De Motu, published in 1670.

Quantity of MOTION, is the same as MOMENTUM, which see. It is a principle maintained by the Cartesians, and some others, that the Creator at the beginning impressed a certain quantity of motion on bodies; and that under such laws, as that no part of it should be lost, but the same portion of motion should be constantly preserved in matter: and hence they conclude, that if any moving body strike another body, the former loses no more of its motion than it communicates to the latter. This position however has been opposed by other philosophers, and perhaps justly, unless the preservation of motion be understood only of the quantity of it as estimated always in the same direction; in which case the principle will hold good. However, the reasoning ought to have proceeded in the contrary order; by first observing from experiment, or otherwise, that when two bodies act upon each other, the one gains exactly the motion which is lost by the other, in the same direction; and hence have drawn the inference, that there is therefore the same quantity of motion preserved in the universe, as was created by God in the beginning; since no body can act upon another, without being itself equally acted on in the opposite or contrary direction.

Equable MOTION, is that by which the moving body proceeds with exactly the same velocity or celerity; passing always over equal spaces in equal times.

The Laws of Equable Motion, are these: 1. The spaces described, or passed over, are in the compound ratio of the velocities, and the times of describing those spaces. So that, if V and v be any two uniform velocities, S and s the spaces described or passed over by them, in the respective times T and t:

then is $S : s :: TV : tv$,
or $20 : 12 :: 4 \times 5 : 3 \times 4$;
taking $T = 4$, $t = 3$, $V = 5$, and $v = 4$.

2. In uniform motions, the time is as the space directly, and as the velocity reciprocally; or as the space divided by the velocity. So that

$$T : t :: \frac{S}{V} : \frac{s}{v} \text{ or } :: Sv : sV.$$

3. The velocity is as the space directly, and the time reciprocally; or as the space divided by the time. That is, $V : v :: \frac{S}{T} : \frac{s}{t}$ or $:: St : sT$.

Accelerated MOTION, is that which continually receives fresh accessions of velocity. And it is said to be uniformly accelerated, when its accessions of velocity are equal in equal times; such as that which is produced by the continual action of one and the same force, like the force of gravity, &c.

Retarded MOTION, is that whose velocity continually decreases. And it is said to be uniformly retarded, when its decrease is continually proportional to the time, or by equal quantities in equal times; like that which is produced by the continual opposition of one and the same force; such as the force of gravity, in uniformly retarding the motion of a body that is thrown upwards.

The laws of motion, uniformly accelerated or retarded, are these: 1. In uniformly varied motions, the space, S or s, is as the square of the time, or as the square of the greatest velocity, or as the rectangle or product of the time and velocity.

That is, $S : s :: T^2 : t^2 :: V^2 : v^2 :: TV : tv$.

2. The velocity is as the time, or as the space divided by the time, or as the square root of the space.

That is, $V : v :: T : t :: \frac{S}{T} : \frac{s}{t} :: \sqrt{S} : \sqrt{s}$.

3. The time is as the velocity, or as the space divided by the velocity, or as the square root of the space.

That is, $T : t :: V : v :: \frac{S}{V} : \frac{s}{v} :: \sqrt{S} : \sqrt{s}$.

4. When a space is described, or passed over, by an uniformly varied motion, the velocity either beginning at nothing, and continually accelerated; or else beginning at some determinate velocity, and continually retarded till the velocity be reduced to nothing; then the space, so described by any body, is exactly equal to half the space that would be run over in the same time by the greatest velocity if uniformly continued for that time. So, for instance, if g denote the space run over in one second, or any other time, by such a variable motion; then $2g$ would be the space that would be run over in one second, or the

same time, by the greatest velocity uniformly continued for the same time; or $2g$ would be the greatest velocity per second which the moving body had. Consequently, if t be any other time, s the space run over in that time, and v the greatest velocity attained in it; then, from the foregoing articles, it will be

$$1'' : t'' :: 2g : 2gt = v \text{ the velocity,}$$

$$\text{and } 1^2 : t^2 :: g : gt^2 = s \text{ the space.}$$

And hence, for any such uniformly varied motions, the relations among the several quantities concerned, will be expressed by the following equations: viz,

$$s = gt^2 = \tfrac{1}{2}tv = \frac{v^2}{4g}; \quad t = \frac{v}{2g} = \frac{2s}{v} = \sqrt{\frac{s}{g}};$$

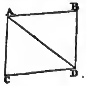
$$v = 2gt = \frac{2s}{t} = 2\sqrt{gs}; \; g = \frac{v}{2t} = \frac{s}{t^2} = \frac{v^2}{4s}.$$

And these equations will hold good in the motion either generated or destroyed by the force of gravity, or by any other uniform force whatever. See also the articles GRAVITY, ACCELERATION, RETARDATION, &c. Again,

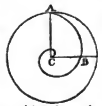
Simple MOTION, is that which is produced by some one power or force only, and is always rectilinear, or in one direction, whether the force be only momentary or continued. And

Compound MOTION, is that which is produced by two or more powers acting in different directions. See COMPOUND, and COMPOSITION *of Motion*.

If a moving body be acted on by a double power; the one according to the direction AB, the other according to AC; then, with the compound motion, or that which is compounded of these two together, it will describe the diagonal AD of the parallelogram, whose sides AB and AC it would have described in the same time with each of the respective powers separately applied.



And if the radius of a circle be made to revolve about the centre C, while a point in the radius sets off from A, and keeps moving along the radius towards the centre; then, by this compound motion, the path of the point will be a kind of spiral ABC.



For the particular laws of motion, arising from the collision of bodies, both elastic and non-elastic, and that where the directions are both perpendicular and oblique, see PERCUSSION.

For CIRCULAR *Motion*, and *the Laws of* PROJECTILES, see the respective words.

For the Motion of Pendulums, and the Laws of Oscillation, see PENDULUM.

Perpetual MOTION, is a motion which is supplied and renewed from itself, without the intervention of any external cause. The celebrated problem of a perpetual motion, consists in the inventing a machine, which has the principle of its motion within itself; and is a problem that has engaged the attention of certain mathematicians for 2000 years; though none perhaps have prosecuted it with attention and earnestness equal to those of the last century. Infinite are the schemes, designs, plans, engines, wheels, &c, to which this long-desired perpetual motion has given birth.

M. Lahire has proved the impossibility of any such machine, and finds that it amounts to this; viz, to find a body which is both heavier and lighter at the same time, or to find a body which is heavier than itself. Indeed there seems but little in nature to countenance all this assiduity and expectation: among all the laws of matter and motion, we know of none yet that seem likely to furnish any principle or foundation for such an effect.

Action and reaction it is allowed are always equal and a body that gives any quantity of motion to another always loses just so much of its own; but under the pre sent state of things, the resistance of the air, the friction c the parts of machines, &c, do necessarily retard ever motion. To continue the motion therefore—either, firs there must be a supply from some foreign cause; which i a perpetual motion is excluded. Or, 2dly, all resistan from the friction of the parts of matter must be remove which necessarily implies a change in the nature of thin Or, 3dly and lastly, there must be some method of gai ing a force equivalent to what is lost, by the artful disp sition and combination of mechanic powers; to wh last point then all endeavours are to be directed: b how, or by what means, such force should be gained, still a mystery. The multiplication of powers or forces is certain, avails nothing; for what is gained in power lost in time, so that the quantity of motion still rema the same. This is an invariable law of nature; by whi nothing is left to art, but the choice of the several com nations that may produce the same effect.

There are various ways by which absolute force may gained; but since there is always an equal gain in op site directions, and no increase obtained in the same dir tion; in the circle of actions necessary to make a perpet movement, this gain must be presently lost, and will serve for the necessary expense of force employed in o coming friction, and the resistance of the medium. therefore, though it could be shown, that in an infi number of bodies, or in an infinite machine, there coul a gain of force for ever, and a motion continued to infir it does not follow that a perpetual movement can be m That which was proposed by M. Leibnitz in the Lei Acts of 1690, as a consequence of the common estima of the forces of bodies in motion, is of this kind, and this and other reasons ought to be rejected. See C FYREUS's *Wheel*, &c, also my Recreations, vol. 2, p 52 on Mechanics.

Animal MOTION, is that by which the situation, fi magnitude, &c, of the parts and members of animal changed. Under these motions, are included all the an functions; as respiration, circulation of the blood, e tion, walking, running, &c.

Animal motions are usually divided into two spe viz, Natural and Spontaneous.

Natural MOTION, is that involuntary one whi effected without the command of the will, by the mechanism of the parts. Such as the motion of the and pulse; the peristaltic motion of the intestines But

Spontaneous, or *Muscular* MOTION, is that which i formed by means of the muscles, at the command c will; which is hence called voluntary motion. Borel a celebrated treatise on this subject, entitled De Animalium.

Intestine MOTION, denotes an agitation of the pa of which a body consists. Some philosophers will every body, and every particle of a body, in con motion. As for fluids, it is the definition they them, that their parts are in continual motion. And as to solids, they infer the like motion from the effluvia continually emitted through their pores. Hence intestine motion is represented to be a motion of the internal and smaller parts of matter, continually excited by some external, latent agent, which of itself is insensible, and only discovers itself by its effects; appointed by nature to be the great instrument of the changes in bodies.

Motion, in Astronomy, is peculiarly applied to the orderly courses of the heavenly bodies.

Mean Motion. See Mean.

The motions of the celestial luminaries are of two kinds: Diurnal, or Common; and Secondary, or Proper.

Diurnal, or *Primary* Motion, is that with which all the heavenly bodies, and the whole mundane sphere, appear to revolve every day about the earth, from east to west. This is also called the motion of the primum mobile, and the common motion, to distinguish it from that rotation which is peculiar to each planet, &c.

Secondary, or *Proper* Motion, is that with which a star, planet, or the like, advances a certain space every day from the west towards the east. See the several motions of each luminary, with the irregularities, &c, of them, under the proper articles, Earth, Moon, Star, &c.

Angular Motion, is that by which the angular position of any thing varies. See Angular.

Horary Motion, is the motion during each hour. See Horary.

Paracentric Motion *of Impetus*. See Paracentric.

Motion *of Trepidation*, &c. See Trepidation and Libration.

MOTIVE *Power*, or *Force*, is the whole power or force acting upon any body, or quantity of matter, to move it; and is proportional to the momentum or quantity of motion it can produce in a given time. And it is thus distinguished from the accelerative force, which is considered as affecting the celerity only.

MOTRIX, something that has the power or faculty of moving. See *Vis Motrix*, and Motion.

MOVEABLE, something susceptible of motion, or that is disposed to be moved. A sphere is the most moveable of all bodies, or is the easiest to be moved on a plane. A door is moveable on its hinges; the magnetic needle on a pin or pivot, &c. Moveable is often used in contradistinction to fixed or fixt.

Moveable *Feasts*, are such as are not always held on the same day of the year or month; though they may be on the same day of the week. Thus, Easter is a moveable feast; being always held on the Sunday which falls upon or next after the first full moon following the 21st of March. See Philos. Trans. No. 240, pa. 185. All the other moveable feasts follow Easter, keeping their constant distance from it; so that they are fixed with respect to this, though moveable through the course of the year. Such are Septuagesima, Sexagesima, Ash-Wednesday, Ascension-Day, Pentecost, Trinity-Sunday, &c.

MOVEMENT, a term often used in the same sense with automaton. The most usual movements for keeping time are clocks and watches: the latter are such as show the parts of time by inspection, and are portable in the pocket; the former such as publish it by sounds, and are fixed as furniture.

Movement, in its popular use, signifies all the inner works of a clock, watch, or other machine, that move, and by that motion carry on the design of the instrument. The movement of a clock, or watch, is the inside; or that part which measures the time, and strikes; exclusive of the frame, case, dial-plate, &c.

The parts common to both of these movements are, the main-spring with its appurtenances, lying in the spring box, and in the middle of it lapping about the spring-arbor, to which one end of it is fastened. On the upper part of the spring-arbor is the endless screw, and its wheel; but in spring clocks this is a ratchet-wheel with its click, that stops it. That part which the main-spring draws, and round which the chain or string is wrapped, is called the fusee, the proper curve for which is the hyperbola; in large works, going with weights, it is cylindrical, and is called the barrel. The small teeth at the bottom of the fusee or barrel, which stop it in winding up, is called the ratchet; and that which stops it when wound up, and is for that end driven up by the spring, the gardegut. The wheels are various: the parts of a wheel are, the hoop or rim; the teeth, the cross, and the collet, or piece of brass soldered on the arbor or spindle on which the wheel is riveted. The little wheels, playing in the teeth of the larger, are called pinions; and their teeth, which are 4, 5, 6, 8, &c, are called leves; the ends of the spindle are called pivots; and the guttured wheel, with iron spikes at bottom, in which the line of common clocks runs, the pulley.

Theory of Calculating the Numbers for Movements.

1. It is first to be observed, that a wheel, divided by its pinion, shows how many turns the pinion has to one turn of the wheel.

2. That from the fusee to the balance the wheels drive the pinions, consequently the pinions run faster, or make more revolutions, than the wheel; but it is the contrary from the great wheel to the dial-wheel.

3. That the wheels and pinions are written down either as vulgar fractions, or in the way of division in common arithmetic: for example, a wheel of 60 teeth, moving a pinion of 5, is set down either thus $\frac{60}{5}$, or thus 5)60, which is better. And the number of turns the pinion has in one turn of the wheel, as a quotient, thus 5) 60 (12. A whole movement may be written as annexed; where the uppermost number expresses the pinion of report 4, the dial-wheel 36, and the turns of the pinion 9; the second, the pinion and great wheel; the third, the second wheel, &c; the fourth, the contrate wheel; and the last, 17, the crown-wheel.

4)	36	(9
5)	55	(11
5)	45	(9
5)	40	(8
		17

4. Hence, from the number of turns any pinion makes, in one turn of the wheel it works in, may be determined the number of turns a wheel or pinion has at any greater distance, viz, by multiplying the quotients together; the product being the number of turns. Thus, suppose the wheels and pinions as in the case above; the quotient 11 multiplied by 9, gives 99, the number of turns in the second pinion 5 to one turn of the wheel 55, which runs concentrical, or on the same spindle, with the pinion 5. Again, 99 multiplied by 8, gives 792, the number of turns the last pinion has to one turn of the first wheel 5. Hence we proceed to find, not only the turns, but the number of beats of the balance, in the time of those turns. For, having found the number of turns the crown-wheel has in one turn of the wheel proposed, those turns multiplied by its notches, give half the number of beats in that one

turn of the wheel. Suppose, for example, the crown-wheel to have 720 turns, to one of the first wheel; this number multiplied by 15, the notches in the crown-wheel, produces 10800, half the number of strokes of the balance in one turn of the first wheel of 80 teeth.—The general division of a movement is, into the clock, and watch parts.

MOULDINGS, in Architecture, are certain projections beyond the naked of a wall, column, wainscot, &c, the assemblage of which forms cornices, door-cases, and other decorations of architecture.

Mouldings, are annexed to great guns by way of ornament, or perhaps in some parts for strength; and probably are derived from the hoops or rings which bound the long iron bars together, anciently used in making cannon.

MOUNTAIN, a considerable eminence of land, elevated above every thing around it. The name is also given to a chain of such masses; as when we speak of Mount Atlas in Africa; or Mount Caucasus, extending from Colchis to the Caspian Sea; or the Pyrenean Mountains, which separate France from Spain; and the Apennine Mountains, traversing the whole of Italy.

Naturalists reckon several kinds of mountains; and conjecture that they have not all the same origin, nor the same date. As, 1st, Those mountains which form a chain, and are covered with snow, are considered as primitives or antediluvian. These greatly exceed other mountains in height; in general their elevation is very sudden, and their ascent very steep and difficult: their shape is pyramidical, crowned with sharp and prominent rocks. No shells, or other organized marine bodies, are found in the upper parts of these primitive mountains, except on the sides near the base. The stone of which they consist is an immense mass of quartz, which penetrates into the bowels of the earth in a direction almost vertical. Of this kind in Europe are the Pyrenees, the Alps, the Apennines, those in Tyrol, in Silesia, in Carpathia, Saxony, Norway, &c. In Asia are the Riphean Mountains, Mounts Caucasus, Taurus, and Libanus. In Africa, Atlas and the Mountains of the Moon; and in America the Apalachian Mountains, and the Andes or Cordilleras. Many of the latter have been the seats of volcanoes.—2d, Another kind of mountains are such as are either detached, or surrounded with groups of little hills, the crust of which is gravelly and confusedly arranged together. These are truncated, or have a wide mouth in the shape of a funnel in the summit, being composed of, or surrounded with heaps of calcined and half vitrified bodies, lava, &c. These appear to have been formed by different strata thrown up into the air, on the eruptions of subterraneous fire: such as the isles of Santorin, Monta-Nuovo, Ætna, Adam's Peak in the island of Ceylon, the Peak of Teneriffe, and many others, have been formed in this manner. —3d, Those mountains, whether arranged in a group or not, the earth or stone of which is disposed in strata, and of one or more colours and substances, are supposed to be produced by the substances deposited slowly and gradually by the waters, or by soil gained at the time of great floods. Though these mountains, formed by strata, sometimes degenerate into little hills, and even become almost flat, they always consist of an immense collection of fossils of different kinds, in good preservation, and which are pretty easily detached from their beds. These fossils, consisting of marine shells, intermixed and confounded with heaps of organised bodies of other species, have an appearance of great disorder, by means of some extraordinary and violent currents. All these phenomena seem to prove that most of these mountains chiefly owe their origin to the sea, which once covered some parts of our continents, now left dry by its retreat.

Of those mountains which extend in a direction north and south, it has been observed that their west side is usually much steeper than the east side; but, in such as extend east and west, the south sides are much steeper than the northern: that the Alps are steeper on their western and southern sides, than on the eastern and northern: that in America the Cordilleras are steepest on the western side. And so in like manner, in all continents, as well as hills and islands, the west and southern sides are commonly the steepest.

Mountains, *Attraction of.* As attraction is found to be a general property of all matter, evincing itself universally by the tendency of all bodies towards the centre of the globe; so particularly in hills, it is shown by their drawing the plumb-line aside from the perpendicular, sideways towards the hill, more or less according to its magnitude, density, and situation. And by the observed effect of these, compared with that of the whole earth, it has been determined that the medium density of this whole globe of earth, is about 5 times that of common water. See the articles Attraction, Density, and Earth, also my Tracts, vol. 2.

Mountains, *Height of.* The following is a list of the measured altitudes of the most remarkable mountains in most parts of the earth, in English feet.

Chimboraço	19595	Source of the Nile	8082
Cayambourou	19391	Monast. St. Bernard	7944
Antisana	19290	Pic de los Reyes	7620
Pichinho	15670	Puy de Domme	5088
Mont Blanc	15662	Mount Hecla	4887
Monte Rosa	15084	Mount Vesuvius	3938
Pic of Teneriffe	14026	Ben Laurs	3858
Aiguille d'Argenture	13402	Ben Moir	3723
Pic d'Ossano	11700	Snowdon	3555
Mount Ætna	10954	Ben Gloe	3472
City of Quito	9977	Schihallen	3461
Pic du Medi	9300	Table Hill, Good Hope	3454
Mount Cenis	9212	Ben Lomond	3180
Canegou	8544	Tinto	2342
Gondar, in Abyssinia	8440	Geneva Lake	1232

Caspian Sea below the ocean 306 feet.

MOYNEAU. See Moineau.

MULLER (John), commonly called Regiomontanus, from Mons Regius, or Koningsberg, a town in Franconia, where he was born in 1436, and he became the greatest astronomer and mathematician of his time. Having first acquired grammatical learning in his own country, he was admitted, while yet a boy, into the academy at Leipsic, where he formed a strong attachment to the mathematical sciences, arithmetic, geometry, astronomy, &c. But not finding proper assistance in these studies at this place, he removed, when only 15 years of age, to Vienna, to study under the celebrated Purbach, the professor there, who read lectures on those sciences with the highest reputation. A strong and affectionate friendship soon took place between them; and our author made such rapid improvement in the sciences, that he was soon able to be assisting to his master, and to become a companion in all his labours. In this manner they spent about ten years together; elucidating obscurities, observing the motions of the heavenly bodies, and comparing and correcting the tables of them; particularly those of Mars, which they found to disagree with the motions, sometimes as much as 2 degrees.

About this time there arrived at Vienna the cardinal Bessarion, who came to negotiate some affairs for the pope; who, being a lover of astronomy, soon formed an acquaintance with Purbach and Regiomontanus. He had begun to form a Latin version of Ptolemy's Almagest, or an epitome of it; but not having time to go on with it himself, he requested Purbach to complete the work, and for that purpose to return with him into Italy, to make himself master of the Greek tongue, which he was as yet unacquainted with. To these proposals Purbach only assented, on condition that Regiomontanus would accompany him, and share in all the labours. They first however, by means of an Arabic version of Ptolemy, made some progress in the work; but this was soon interrupted by the death of Purbach, which happened in 1461, in the 39th year of his age. The whole task then devolved on Regiomontanus, who finished the work, at the request of Purbach, made to him when on his death-bed. This work our author afterwards revised and perfected at Rome, when he had learned the Greek language, and consulted the commentator Theon, &c.

Regiomontanus accompanied the cardinal Bessarion in his return to Rome, being then near 30 years of age. Here he applied himself diligently to the study of the Greek language; not neglecting however to make astronomical observations and compose various works in that science; as his Dialogue against the Theories of Cremonensis. The cardinal going to Greece soon after, Regiomontanus went to Ferrara, where he continued the study of the Greek language under Theodore Gaza; who explained to him the text of Ptolemy, with the commentaries of Theon; till at length he became so perfect in it, that he could compose verses, and read it like a critic.—In 1463 he went to Padua, where he became a member of the university; and, at the request of the students, explained Alfraganus, an Arabian philosopher.—In 1464 he removed to Venice, to meet and attend his patron Bessarion. Here he wrote, with great accuracy, his Treatise on Triangles, and a Refutation of the Quadrature of the Circle, which cardinal Cusan pretended he had demonstrated. The same year he returned with Bessarion to Rome; where he made some stay, to procure the most curious books: those which he could not purchase, he took the pains to transcribe, for he wrote with great facility and elegance; and others he got copied at a great expense. For as he was certain that none of these books could be had in Germany, he thought on his return thither, he would at his leisure translate and publish some of the best of them. During this time too he had a severe contest with George Trabezonde, whom he had greatly offended by animadverting on some passages in his translation of Theon's Commentary.

Being now weary of rambling about, and having procured a great number of manuscripts, which was one great object of his travels, he returned to Vienna, and performed for some time the offices of his professorship, by reading of lectures &c. After being thus employed, he went to Buda, on the invitation of Matthias king of Hungary, who was a great lover of letters and the sciences, and had founded a rich and noble library there: for he had bought up all the Greek books that could be found on the sacking of Constantinople; also those that were brought from Athens, or wherever else they could be met with through the whole Turkish dominions, collecting them all together into a library at Buda. But a war breaking out in this country, he looked out for some other place to settle in, where he might pursue his studies, and for this purpose he retired to Noremberg. He tells us, that the reasons which induced him to desire to reside in this city the remainder of his life were, that the artists there were dextrous in fabricating his astronomical machines; and besides, he could from thence easily transmit his letters by the merchants into foreign countries. Being now well versed in all parts of learning, and having made the utmost proficiency in mathematics, he determined to occupy himself in publishing the best of the ancient authors, as well as his own lucubrations. For this purpose he set up a printing-house, and formed a nomenclature of the books he intended to publish, which still remains.

Here that excellent man, Bernard Walther, one of the principal citizens, who was well skilled in the sciences, especially astronomy, cultivated an intimacy with Regiomontanus; and as soon as he understood those laudable designs of his, he took upon himself the expense of constructing the astronomical instruments, and of erecting a printing-house. And first he ordered astronomical rules to be made of tin, for observing the altitudes of the sun, moon, and planets. He next constructed a rectangular, or astronomical radius, for taking the distance of those luminaries. Then an armillary astrolabe, such as was used by Ptolemy and Hipparchus, for observing the places and motions of the stars. Lastly, he made other smaller instruments, as the torquet, and Ptolemy's meteoroscope, with some others which had more of curiosity than utility in them. From this apparatus it evidently appears, that Regiomontanus was a most diligent observer of the laws and motions of the celestial bodies, if there were not still stronger evidences of it in the accounts of the observations themselves which he made with them.

With regard to the printing-house, which was the other part of his design in settling at Noremberg, as soon as he had completed it, he put to press two works of his own, and two others. The latter were, The New Theories of his master Purbach, and the Astronomicon of Manilius. And his own were, the New Calendar, in which were given (as he says in the index of the books which he intended to publish) the true conjunctions and oppositions of the luminaries, their eclipses, their true places every day, &c. His other work was his Ephemerides, of which he thus speaks in the said index: "The Ephemerides, which is vulgarly called an Almanac, for 30 years: where you may every day see the true motion of all the planets, of the moon's nodes, with the aspects of the moon to the sun and planets, the eclipses of the luminaries; and in the fronts of the pages are marked the latitudes." He published also most acute commentaries on Ptolemy's Almagest: a work which cardinal Bessarion so highly valued, that he scrupled not to esteem it worth a whole province. He prepared also new versions of Ptolemy's Cosmography; and at his leisure hours examined and explained works of another nature. He inquired how high the vapours are carried above the earth, which he fixed to be not more than 12 German miles. He set down observations of two comets that appeared in the years 1471 and 1472.

In 1474, pope Sixtus the 4th conceived a design of reforming the calendar; and sent for Regiomontanus to Rome, as the most proper and able person to accomplish his purpose. Regiomontanus was very unwilling to interrupt the studies, and printing of books, he was engaged in at Noremberg; but receiving great promises from the pope, who also for the present named him bishop of Ratisbon, he at length consented to go. He arrived at Rome in 1475, but died there the year after, at only 40 years of age; not without a suspicion of having been poisoned by the sons of George Trabezonde, in revenge for the death of their father, which was said to have been caused by the grief he felt on account of the criticisms made by Regiomontanus on his translation of Ptolemy's Almagest.

Purbach first of any reduced the trigonometrical tables of sines, from the old sexagesimal division of the radius, to the decimal scale. He supposed the radius to be divided into 600,000 equal parts, and computed the sines of the arcs to every ten minutes, in such equal parts of the radius, by the decimal notation. This project of Purbach was perfected by Regiomontanus; who not only extended the sines to every minute, the radius being 600,000, as designed by Purbach, but afterwards, disliking that scheme, as evidently imperfect, he computed them likewise to the radius 1,000,000, for every minute of the quadrant. Regiomontanus also introduced the tangents into trigonometry, the canon of which he called fœcundus, because of the many great advantages arising from them. Besides these things, he enriched trigonometry with many theorems and precepts. Indeed, excepting for the use of logarithms, the trigonometry of Regiomontanus is but little inferior to what ours was, before the improvements made in it by Euler. His Treatise, on both Plane and Spherical Trigonometry, is in 5 books; it was written about the year 1464, and printed in folio at Noremberg in 1533. In the 5th book are various problems concerning rectilinear triangles, some of which are resolved by means of algebra: a proof that this science was not wholly unknown in Europe before the treatise of Lucas De Burgo.

Regiomontanus was author of some other works besides those already mentioned. Peter Ramus, in the account he gives of the admirable works attempted and performed by Regiomontanus, tells us, that in his workshop at Noremberg there was an automaton in perpetual motion: that he made an artificial fly which, taking its flight from his hand, would fly round the room, and at last, as if weary, would return to his master again: that he fabricated an eagle, which, on the emperor's approach to the city, he sent out, high in the air, a great way to meet him, and that it kept him company to the gates of the city. Let us no more wonder, adds Ramus, at the dove of Archytas, since Noremberg can show a fly, and an eagle, armed with geometrical wings. Nor are those famous artificers, who were formerly in Greece and Egypt, any longer of such account, since Noremberg can boast of her Regiomontanuses. For Wernerus first, and then the Schoneri, father and son, afterwards, revived the spirit of Regiomontanus.

MULTANGULAR FIGURE, is one that has many angles, and consequently many sides also. These are otherwise called polygons.

MULTILATERAL FIGURES, are such as have many sides, or more than four sides.

MULTINOMIAL, or MULTINOMIAL *Roots*, are such as are composed of many names, parts, or members; as, $a + b + c + d$ &c.—For the raising an infinite multinomial to any power, or extracting any root out of such power, see a method by M. Demoivre, in the Philos. Trans. No. 230. See also POLYNOMIAL.

MULTIPLE, MULTIPLEX, a number which comprehends some other number several times. Thus, 6 is a multiple of 2, this being contained in 6 just 3 times. Also 12 is a common multiple of 6, 4, and 3; comprehending the first twice, second thrice, and the third four times.

MULTIPLE *Ratio* or *Proportion*, is that which is between multiple numbers &c. If the less term of a ratio be an aliquot part of the greater, the ratio of the greater to the less is called multiple; and that of the less to the greater submultiple.—A submultiple number, is that which is contained in the multiple. Thus, the numbers 2, 3, and 4 are submultiples of 12 and 24.—Duple, triple, &c ratios; as also subduples, subtriples, &c, are so many species of multiple and submultiple ratios.

MULTIPLE *Superparticular Proportion*, is when one number or quantity contains another more than once, and a certain aliquot part; as 10 to 3, or $3\frac{1}{3}$ to 1.

MULTIPLE *Superpartient Proportion*, is when one number or quantity contains another several times, and some parts besides; as 29 to 6, or $4\frac{5}{6}$ to 1.

MULTIPLICAND, is one of the two factors in the rule of multiplication, being that number given to be multiplied by the other, called the multiplicator, or multiplier.

MULTIPLICATION, is, in general, the taking or repeating of one number or quantity, called the multiplicand, as often as there are units in another number, called the multiplier; and the number or quantity resulting from the multiplication, is called the product of the two foregoing numbers or factors.—Multiplication is a compendious addition; performing at once, what in the usual way of addition would require many operations; for the multiplicand is only added to itself, or repeated, as often as is expressed by the units in the multiplier. Thus, if 6 were to be multiplied by 5, the product is 30, which is the sum arising from the addition of the number 6 five times to itself.—In every multiplication, 1 is in proportion to the multiplier, as the multiplicand is to the product.

Multiplication is of various kinds, in whole numbers, in fractions, decimals, algebra, &c.

1. MULTIPLICATION *of Whole Numbers*, is performed by the following rules: When the multiplier consists of only one figure, set it under the first, or right-hand figure, of the multiplicand; then, drawing a line under it, begin at the said first figure, and multiply every figure of the multiplicand by the multiplier; setting down the several products below the line, proceeding orderly from right to left. But if any of these products amount to 10, or several 10's, either with or without some overplus, then set down only the overplus, or set down 0 if there be none; and carry, to the next product, as many units as the former contained of tens. Thus, to multiply 35092 by 4.

Multiplicand	35092
Multiplier	4
Product	140368

When the multiplier consists of several figures, multiply the multiplicand by each figure of it, as before, and place the several lines of products below each other in such order, that the first figure of each line may fall straight under its respective multiplier, or multiplying figure; then add these several lines of products together, as they stand, and the sum of them all will be the product of the whole multiplication. Thus, to multiply 63017 by 236:

Multiplicand - -	63017
Multiplier - -	236
Product of 63017 by 6	378102
Product of 63017 by 30	189051
Product of 63017 by 200	126034
Whole product	14872012

The several lines of products may be set down in any order, or any of them first, and any other of them second, &c; for the order of placing them can make no difference in the sum total. There are many abbreviations, and peculiar cases, according to circumstances, which may be seen in most books of arithmetic. The mark or character now used for multiplication, is either the × cross, or a single point . ; the former being introduced by Oughtred, and the latter I think by Leibnitz.

To Prove MULTIPLICATION. This may be done various ways; either by dividing the product by the multiplier, then the quotient will be equal to the multiplicand; or divide the same product by the multiplicand, and the quotient will come out equal to the multiplier: or in general divide the product by either of the two factors, and the quotient will be equal to the other factor, when the operations are all right. But the more usual, and compendious way of proving multiplication, is by what is called the cross, by casting out the nines; which is performed thus: Add the figures of the multiplicand all together, and as often as the sum amounts to 9, reject it, and set down the last overplus as in the margin; this in the foregoing example is 8. Then do the same by the multiplier, setting down the last overplus, which is 2, on the right of the former remainder 8. Next multiply these two remainders, 2 and 8, together, and from their product 16, cast out the 9, and there remains 7, which set down over the two former. Lastly, add up, in the same manner, all the figures of the whole product of the multiplication, viz 14872012, casting out the 9's, and then there remains 7, to be set down under the two first remainders. Thus when the figure at top, is the same as that at bottom, as they are here both 7's, the work it may be presumed is right; but if these two figures should not be the same, it is certainly wrong.

	7	
8		2
	7	

The above method of proving multiplication depends on a particular property of the number 9: which is this. If the sum of the digits of any number be divisible by 9, the number itself is also divisible by 9; and consequently the sum of the digits of any number being divided by 9, leaves the same remainder as the number itself when divided by 9. Another method is derived from a peculiar property of the number 11, which is this. When a number is divisible by 11, the sum of the 1st, 3d, &c, digits, is equal to the sum of the 2d, 4th, &c, digits, or the one exceeds the other by some exact multiple of 11. Consequently any number whatever when divided by 11, will leave the same remainder as the difference of the two sums when divided by that number; observing always to subtract the latter sum from the former, or from the former plus some multiple of 11, when the sum of the digits in the 2d, 4th, &c, places is the greatest. Whence the following rule. Cast all the 11's out of the sums of the digits, both in the even and odd places of the multiplicand, and subtract the former remainder from the latter, or from the latter plus 11, and reserve the difference; do exactly the same with the multiplier and product. Multiply the two first differences together, and cast all the 11's out of the result, so shall this last remainder be the same as that before found in the product, if the work be right. Thus in the above example:

	Multiplic.	Multiplier	Product		
Sum of odd digits	13	8	13		1
Sum of even digits	4	3	12	9	5
Differences	9	5	1		1

And the product 9 × 5 ÷ 11, leaving the remainder 1, which being the same as the remainder of the product, indicates that the work is right.

2. *To Multiply Money, or any other thing, consisting of different Denominations together, by any number, usually called Compound Multiplication.* -Begin at the lowest denomination, and multiply the number of each name separately by the multiplier, setting down the products below them. But if any of these products amount to as much as 1 or more of the next higher denominations, carry so many to the next product, and set down only the overplus.

If the multiplier exceeds 12, then resolve it into its factors, if it be a compound number; and multiply successively by those factors; but if the given multiplier be not a compound number, then resolve the next greater or less compound number into its factors, and multiply with those factors as above; and from the result deduct, or add, so many times the multiplicand, as this last compounded number is greater or less than the given multiplier. Also if there are fractional parts in the given multiplier, take such parts of the multiplicand as these are of a unit, which added to the product will give the answer sought; as will appear in the following examples.

Ex. 1. Multiply 1*l.* 12*s.* 4½*d.*
by 9
*L.*14 11 4½

Ex. 2. Multiply 12*s.* 7½*d.* by 24
24 = 6 × 4   4
2 10 6
6
*L.*15 3 0

Multiply 1*l.* 13*s.* 8*d.* by 29½
29½ = 4 × 7 + 1 + ½   4

4 =	6	14	8
			7
28 =	47	2	8
1 =	1	13	8
½ =	0	16	10
29½ =	*L.*49	13	2

3. *To Multiply Vulgar Fractions.*—Multiply all the given numerators together for the numerator, and all the denominators together for the denominator of the product sought.

Thus, $\frac{2}{3}$ multiplied by $\frac{4}{5}$, or $\frac{2}{3} \times \frac{4}{5} = \frac{8}{15}$.

And $\frac{3}{5} \times \frac{2}{5} \times \frac{3}{7} = \frac{18}{175}$.

And here it may be noted that, when there are any common numbers in the numerators and denominators, these may be omitted in both, which will make the operation shorter, and bring out the whole product in a fraction much simpler or in lower terms. Thus,

$\frac{2}{3} \times \frac{3}{4} \times \frac{5}{6}$, become $\frac{2 \times 5}{4 \times 6} = \frac{10}{24}$ or $\frac{5}{12}$, by leaving out the two 3's.

Also, when any numerators and denominators will both abbreviate or divide by one and the same number, let them be divided, and the quotients used instead of them. So, in the above example, after omitting the two 3's, let the 2 and 6 be both divided by 2, and use the quotients 1 and 3 instead of them, so shall the expression become $\frac{1 \times 5}{4 \times 3} = \frac{5}{12}$, as before.

4. *To Multiply Decimals.*—Multiply the given numbers together the same as if they were whole numbers, and point off as many decimals in the whole product as there are in both factors; as in the annexed example, where the number of decimals is five, because there are three in the multiplicand, and two in the multiplier.—When it happens that there are not so many figures in the product as are equal to the number of decimals in both factors, then prefix as many ciphers as will supply the defect.

5. *Cross* Multiplication, otherwise called *Duodecimal Arithmetic*, is the multiplying of numbers together whose subdivisions proceed by 12's; as feet, inches, and parts, that is 12th-parts, &c; a rule of frequent use in squaring, or multiplying together the dimensions of the works of bricklayers, carpenters, and other artificers. *For Example.* To multiply 5 feet 3 inches by 2 feet 4 inches. Set them down as in the margin, and multiply all the parts of the multiplicand by each part of the multiplier; thus, 2 times 3 make 6 inches, and 2 times 5 make 10 feet; then 4 times 3 make 12 parts, or 1 inch to carry; and 4 times 5 make 20, and 1 to carry makes 21 inches, or 1 f. 9 inc. to set down below the former line: Lastly adding the two lines together, the whole sum or product amounts to 12 f. 3 inch.—See Duodecimals.

2	4
10	6
1	9
12	3

6. Multiplication *in Algebra.* This is performed, 1. When the quantities are simple, by only joining the letters together like a word; and if the simple quantities have any coefficients or numbers joined with them, multiply the numbers together, and prefix the product of them to the letters so joined together. But, in algebra, we have not only to attend to the quantities themselves, but also to the signs of them; and the general rule for the signs is this: When the signs are alike, or the same, either both + or both −, then the sign of the product will always be +; but when the signs are different, or unlike, the one +, and the other −, then the sign of the product will be −. Hence these

Examples.

Mult.	$+a$	$-2a$	$+6x$	$-8x$	$-3ab$
By	$+b$	$-4b$	$-3a$	$+5a$	$-5ac$
Products	$+ab$	$+8ab$	$-18ax$	$-40ax$	$+15a^2bc$

2. In compound quantities, multiply every term or part of the multiplicand by each term separately of the multiplier, and set down all the products with their signs, collecting always into one sum as many terms as are similar or like to one another. And it is usual in algebra, to begin to multiply on the left hand, and thence proceed towards the right; being directly contrary to the method in multiplication of numbers.

Examples.

$a + b$	$a - b$	$a + b$
$a + b$	$a - b$	$a - b$
$a^2 + ab$	$a^2 - ab$	$a^2 + ab$
$\quad + ab + b^2$	$\quad - ab + b^2$	$\quad - ab - b^2$
$a^2 + 2ab + b^2$	$a^2 - 2ab + b^2$	$a^2 \quad * \quad - b^2$

$2a - 3b$	$2a + 4x$	$a^2 - ax$
$4a + 5b$	$2a - 4x$	$2a + 2x$
$8a^2 - 12ab$	$4a^2 + 8ax$	$2a^3 - 2a^2x$
$\quad + 10ab - 15b^2$	$\quad - 8ax - 16x^2$	$\quad + 2a^2x - 2ax^2$
$8a^2 - 2ab - 15b^2$	$4a^2 \quad * \quad - 16x^2$	$2a^3 \quad * \quad - 2ax^2$

3. In surd quantities, if the terms can be reduced to a common surd, the quantities under each may be multiplied together, and the mark of the same surd prefixed to the product; but if not, then the different surds may be set down with the mark of multiplication between them, to denote their product.

Examples.

$7\sqrt{ax}$	$\sqrt{7}$	$\sqrt[3]{7ab}$	$\sqrt{12a}$	$6a\sqrt{2cx}$
$5\sqrt{cx}$	$\sqrt{5}$	$\sqrt[3]{4ac}$	$\sqrt{3a}$	$2b\sqrt{3ax}$
$35\sqrt{acx^2}$	$\sqrt{35}$	$\sqrt[3]{28a^2bc}$	$\sqrt{36a^2} = 6a$	$12ab\sqrt{6acx^2}$

4. Powers or roots of the same quantity are multiplied together, by adding their exponents.

Thus, $a^2 \times a^3 = a^5$; and $(a + x)^3 \times (a + x)^5 = (a + x)^7$: also $x^2 \times x^{\frac{1}{2}} = x^{\frac{5}{2}}$; and $a^{\frac{1}{2}} \times a^{\frac{1}{2}} = a^1$ or a.

To Multiply Numbers together by Logarithms.—This is performed by adding together the logarithms of the given numbers, and taking the number answering to that sum, which will be the product sought.

Descartes, at the beginning of his Geometry, performs multiplication (and indeed all the other common arithmetical rules) in geometry, or by lines; but this is no more than taking a 4th proportional to three given lines, of which the first represents unity, and the 2d and 3d the two factors or terms to be multiplied, the product being expressed by the 4th proportional; because, in every multiplication, unity or 1 is to either of the two factors, as the other factor is to the product.

MULTIPLIER, or Multiplicator, is the number or quantity which multiplies another, called the multiplicand, in any operation of multiplication.

MUNSTER (Sebastian), an eminent German divine and mathematician, was born at Ingelheim in 1489. At the age of 14 he was sent to Heidelberg to study. Two years after, he entered the convent of the Cordeliers; where he assiduously studied divinity, mathematics, and geography. He was the first who published a Chaldee Grammar and Lexicon; and he shortly after produced a Talmudic Dictionary. He afterwards became professor of the Hebrew language at Basil. He was one of the first who attached himself to Luther, and embraced Protestantism: yet behaved himself with great moderation; never concerning himself with their disputes; but shut himself up at home and pursued his favourite studies, which were mathematics, natural philosophy, with the Hebrew and other Oriental languages. He published a great number of books on these subjects; particularly, a Latin version, from the Hebrew, of all the books of the Old Testament, with learned notes, printed at Basil in 1534 and 1546; Josephus's History of the Jews in Latin; a Treatise of Dialling, in folio, 1536; Universal Cosmography, in 6 books folio, Basil 1550. For these works he was styled the German Strabo; as he was the German Esdras, for his Oriental writings.

Munster was a meek, pacific, studious, retired man, who wrote a great number of books, but never meddled in controversy.—He died of the plague at Basil, in 1552, at 63 years of age.

MURAL-*Arch*, or Instrument, or Quadrant, is one that is fixed against a wall or pillar, such as is employed in fixed observatories.

MURDERERS, a small species of ordnance once used on shipboard; but now out of use.

MUSIC, the science of sound, considered as capable of producing melody, or harmony. Among the ancients, music was taken in a much more extensive sense than among the moderns: what we call the science of music, was by the ancients rather called Harmonica.

Music is one of the seven sciences called liberal, and comprehended also among the mathematical sciences, as having for its object discrete quantity or number; not however considering it in the abstract, like arithmetic; but in relation to time and sound, with intent to constitute a delightful melody.

This science is also Theoretical and Practical. Theoretical, which examines the nature and properties of concords and discords, explaining the proportions between them by numbers. And Practical, which teaches not only composition, or the manner of composing tunes, or airs; but also the art of singing with the voice, and playing on musical instruments.

It appears that music was one of the most ancient of the arts; and, of all others, vocal music must doubtless have been the first kind. For man had not only the various tones of his own voice to make his observations on, before any other art or instrument was invented, but had the various natural strains of birds to give him occasion to improve his own voice, and the modulations of sounds it was capable of. The first invention of wind instruments Lucretius ascribes to the observation of the winds whistling in the hollow reeds. As for other kinds of instruments, there were so many occasions for cords or strings, that men could not be long in observing their various sounds; which might give rise to stringed instruments. And for the pulsative instruments, as drums and cymbals, they might arise from the observation of the naturally hollow noise of concave bodies.

As to the inventors and improvers of music, Plutarch, in one place, ascribes the first invention of it to Apollo; and in another place to Amphion, the son of Jupiter and Antiope. The latter indeed, it is generally allowed, first brought music into Greece, and invented the lyre. To him succeeded Chiron, the demigod; then Demodocus; Hermes Trismegistus; Olympus; and Orpheus, whom some make the first introducer of music into Greece, and the inventor of the lyre: to whom they add Phemius, Thales, and Thamgris, who, it has been said, was the first inventor of instrumental music without singing.

These were the eminent musicians before Homer's time: others of a later date were, Terpander, who was contemporary with Lycurgus, and set his laws to music; to whom also some attribute the first institution of musical modes, and the invention of the lyre: also, Lasus Hermionensis, Melanippides, Philoxenus, Timotheus, Phrynnis, Epigonius, Lysander, Simmicus, and Diodorus; who were all of them considerable improvers of music. Lasus, it is said, was the first author who wrote upon music, in the time of Darius Hystaspis; Epigonius invented an instrument of 40 strings, called the Epigonium. Simmicus also invented an instrument of 35 strings, called a Simmicium; Diodorus improved the tibia, by adding new holes; and Timotheus the lyre, by adding a new string; for which he was fined by the Lacedemonians.

As the accounts we have of the inventors of musical instruments among the ancients are very obscure, so also are the accounts of those instruments themselves; of most of them indeed we know little more than the bare names. The general division of instruments is, into stringed instruments, wind instruments, and those of the pulsatile kind. Of stringed instruments, mention is made of the lyra or cithara, the psalterium, trigonum, sambuca, pectis, magas, barbiton, testudo, epigonium, simmicium, and panderon; which were all struck with the hand, or a plectrum. Of wind instruments, were the tibia, fistula, hydraulic organs, tubæ, cornua, and lituus. And the pulsatile instruments were the tympanum, cymbalum, crepitaculum, tintinnabulum, crotalum, and sistrum.

Music has ever been in the highest esteem in all ages, and among all people; nor could authors express their opinion of it strongly enough, but by inculcating that it was used in heaven, and as one of the principal entertainments of the gods, and the souls of the blessed. The effects ascribed to it by the ancients are almost miraculous: by its means, it has been said, diseases have been cured, unchastity corrected, seditions quelled, passions raised and calmed, and even madness occasioned. Athenæus assures us, that anciently all laws, divine and civil, exhortations to virtue, the knowledge of divine and human things, with the lives and actions of illustrious men, were written in verse, and publicly sung by a chorus to the sound of instruments; which was found the most effectual means to impress morality on the minds of men, and a right sense of their duty.

Dr. Wallis has endeavoured to account for the surprising effects attributed to the ancient music; and ascribes them chiefly to the novelty of the art, and the hyperboles of the ancient writings: nor does he doubt, but the modern music, in like cases, would produce effects at least as considerable as the ancient. The truth is, we can match most of the ancient stories of this kind in the modern histories. If Timotheus could excite Alexander's fury with the Phrygian mode, and soothe him into indolence with the Lydian; a more modern musician has driven Eric, king of Denmark, into such a rage, as to kill his best servants. Dr. Niewentyt speaks of an Italian who, by varying his music from brisk to solemn, and the contrary, could so move the soul, as to cause distraction and madness; and Dr. South has founded his poem, called Musica Incantans, on an instance he knew of the same kind.

Music however is found not only to exert its force on the affections, but on the parts of the body also: witness the Gascon knight, mentioned by Mr. Boyle, who could not contain his water at the playing of a bagpipe; and the woman, mentioned by the same author, who would burst into tears at the hearing of a certain tune, with which other people were but a little affected. To say nothing of the trite story of the Tarantula, we have an instance, in the History of the Academy of Sciences, of a musician being cured of a violent fever, by a little concert occasionally played in his room.

Nor are our minds and bodies alone affected with sounds, but even inanimate bodies are so. Kircher speaks of a large stone, that would tremble at the sound of one particular organ pipe; and Morhoff mentions one Petter, a Dutchman, who could break rummer-glasses with the tone of his voice. Mersenne also mentions a particular part of a pavement, that would shake and tremble, as if the earth would open, when the organs played. Mr. Boyle adds, that seats will tremble at the sound of organs; that he has felt his hat do so under his hand, at certain notes both of organs and discourse; and that he was well informed every well-built vault would thus answer to some determinate note.

It has been disputed among the learned, whether the ancients or moderns best understood and practised music. Some maintain that the ancient art of music, by which such wonderful effects were performed, is quite lost; and others, that the true science of harmony is now arrived at much greater perfection than was known or practised among the ancients. This point seems no other way to be determinable but by comparing the principles and practice of the one with those of the other. As to the theory or principles of harmonics, it is certain we understand it better than the ancients; because we know all that they knew, and have improved considerably on their foundations. The great dispute then lies on the practice; with regard to which it may be observed, that among the ancients, music, in the most limited sense of the word, included harmony, rythmus, and verse; and consisted of verses sung by one or more voices alternately, or in choirs, sometimes with the sound of instruments, and sometimes by voices only. Their musical faculties, we have just observed, were melopœia, rythmopœia, and poesis; the first of which may be considered under two heads, melody and symphony. As to the latter, it seems to contain nothing but what relates to the conduct of a single voice, or making what we call melody. It does not appear that the ancients ever thought of the concert, or harmony of parts; which is a modern invention, for which we are beholden to Guido Aretine, a Benedictine friar.

Not that the ancients never joined more voices or instruments than one in the same symphony; but that they never joined several voices so as that each had a distinct and proper melody, which made among them a succession of various concords, and were not in every note unisons, or at the same distance from each other as octaves. This last indeed agrees to the general definition of the word symphonia; yet it is plain that in such cases there is but one song, and all the voices perform the same individual melody. But when the parts differ, not by the tension of the whole, but by the different relations of the successive notes, this is the modern art, which requires so peculiar a genius, and on which account the modern music seems to have much the advantage of the ancient. For further satisfaction on this head, see Kircher, Perrault, Wallis, Malcolm, Cerceau, and others; who unanimously agree, that after all the pains they have taken to know the true state of the music of the ancients, they could not find the least reason to think there was any such thing in their days as music in parts.

The ancient musical notes are very mysterious and perplexed: Boethius and Gregory the Great first put them into a more easy and obvious method. In the year 1204, Guido Aretine, a Benedictine of Arezzo in Tuscany, first introduced the use of a staff with five lines, on which, with the spaces, he marked his notes by setting a point up and down upon them, to denote the rise and fall of the voice: though Kircher says this artifice was in use before Guido's time.

Another contrivance of Guido's was to apply the six syllables, *ut*, *re*, *mi*, *fa*, *sol*, *la*, which he took out of the Latin hymn,

UT queant laxis RESonare fibris
MIra gestorum FAmuli tuorum,
SOLve polluti LAbii reatum,
O Pater Alme.

We find another application of them in the following lines.

UT RElevet MIserum FAtum, SOLitosque LAbores
Aevi, sit dulcis musica noster amor.

Besides his notes of music, by which, according to Kircher, he distinguished the tones, or modes, and the seats of the semitones, he also invented the scale, and several musical instruments, called polyplectra, as spinets and harpsichords.

The next considerable improvement was in 1330, when Joannes Muria, or de Muris, doctor at Paris (or as Bayle and Gesner make him, an Englishman), invented the different figures of notes, which express the times or length of every note, at least their true relative proportions to one another, now called longs, breves, semi-breves, crotchets, quavers, &c.

The most ancient writer on music was Lasus Hermionensis; but his works, as well as those of many others, both Greek and Roman, are lost. Aristoxenus, disciple of Aristotle, is the earliest author extant on the subject: after whom came Euclid, author of the Elements of Geometry; and Aristides Quintilianus wrote after Cicero's time. Alypius stands next; after him Gaudentius the philosopher, and Nicomachus the Pythagorean, and Bacchius. Of which seven Greek authors we have a fair copy, with a translation and notes, by Meibomius. Ptolemy, the celebrated astronomer, wrote in Greek on the principles of harmonics, about the time of the emperor Antoninus Pius. This author keeps a medium between the Pythagoreans and Aristoxenians. He was succeeded at a considerable distance by Manuel Bryennius.

Of the Latins, we have Boetius, who wrote in the time of Theodoric the Goth; and one Cassiodorus, about the same time; Martianus, and St. Augustine, not far remote. And of the moderns are Zarlin, Salinas, Vincenzo Galileo, Doni, Kircher, Mersenne, Paran, De Caux, Perrault, Descartes, Wallis, Holder, Malcolm, Rousseau, &c.

MUSICAL *Numbers*, are the numbers 2, 3, and 5, together with their composites. They are so called, because all the intervals of music may be expressed by such numbers. This is now generally admitted by musical theorists. Mr. Euler seems to suppose, that 7 or other primes might be introduced; but he speaks of this as a doubtful and difficult matter. Here 2 corresponds to the octave, 3 to the fifth, or rather to the 12th, and 5 to the third major, or rather the seventeenth. From these three may all other intervals be found.

MUSICAL *Proportion*, or Harmonical Proportion, is when, of four terms, the first is to the 4th, as the difference of the 1st and 2d is to the difference of the 3d and 4th: as 2, 3, 4, and 8 are in musical proportion, because 2 : 8 : : 1 : 4. And hence, if there be only three terms, the middle term supplying the place of both the 2d and 3d, the 1st is to the 3d, as the difference of the 1st and 2d, is to the difference of the 2d and 3d: as in these 2, 3, 6; where 2 : 6 : : 1 : 3. See HARMONICAL *Proportion*.

MUSSCHENBROEK (PETER), a very distinguished natural philosopher and mathematician, was born at Utrecht about the year 1700. He was first professor of these sciences in his own university, and was afterwards invited to the chair at Leyden, which he filled with reputation and honour till his death, which happened in 1761. He was a member of several academies, particularly the Academy of Sciences at Paris. He published several works in Latin, all of them displaying his great penetration and accuracy. As,

1. His Elements of Physico-Mathematics, in 1726.
2. Elements of Physics, in 1736.
3. Institutions of Physics; containing an abridgment of the new discoveries made by the moderns; in 1748.
4. Introduction to Natural Philosophy; which he began to print in 1760; and which was completed and published at Leyden, in 1762, by M. Lulofs, after the death of the author. It was translated into French by M. Sigaud Delafond, and published at Paris in 1769, in 3 vols. 4to; under the title of A Course of Experimental and Mathematical Physics.

He had also several papers, chiefly on meteorology, printed in the volumes of Memoirs of the Academy of Sciences, viz, in those of the years 1734, 1735, 1736, 1753, 1756, and 1760.

MUTULE, a kind of square modillion in the Doric frize.

MYOPS, one who is near-sighted, or purblind, from whatever cause it may happen; either from too great a convexity of the cornea, or from too great length of the bulb, &c, causing the adunation of the rays of light in a focus before the retina.

MYRIAD, the number of 10,000, or ten thousand.

N.

NABONASSAR, first king of the Chaldeans or Babylonians; memorable for the Jewish era which bears his name, which began on Wednesday February 26th in the 3967th year of the Julian period, or 747 years before Christ; the years of this epoch being Egyptian ones, of 365 days each. This is a remarkable era in chronology, because Ptolemy assures us there were astronomical observations made by the Chaldeans from Nabonassar to his time; also Ptolemy, and the other astronomers, account their years from that epoch.

The Babylonians having revolted from the Medes, who had overthrown the Assyrian monarchy, did, under Nabonassar, found a dominion, which was much increased under Nebuchadnezzar. It is probable this Nabonassar is that Baladan in the 2d Book of Kings, xx, 12, father of Merodach, who sent ambassadors to Hezekiah. See 2 Chron. xxii.

NADIR, that point of the heavens diametrically under our feet, or opposite to the zenith, which is directly over our heads. The zenith or nadir are the two poles of the horizon, each being 90° distant from it.

The Sun's NADIR, is the axis of the cone projected by the shadow of the earth: so called, because that axis being prolonged, gives a point in the ecliptic diametrically opposite to the sun.

NAKED, in Architecture, as the Naked of a Wall, &c. is the surface, or plane, from whence the projectures arise; or which serves as a ground to the projectures.

NAPIER or NEPER (JOHN), baron of Merchiston in Scotland, the inventor of logarithms, was the eldest son of sir Archibald Napier of Merchiston, and born in the year 1550. Having given early indications of great natural parts, his father was careful to have them cultivated by a liberal education. After going through the ordinary course of studies at the university of St. Andrews, he made the tour of France, Italy, and Germany. On his return to his native country, his literature and other fine accomplishments soon rendered him conspicuous; he however retired from the world to pursue literary researches, in which he made an uncommon progress, as appears by the several useful discoveries with which he afterwards favoured mankind. He chiefly applied himself to the study of mathematics; without however neglecting that of the Scriptures; in both of which he discovered the most extensive knowledge and profound penetration. His Essay on the Book of the Apocalypse indicates the most acute investigation; though time hath discovered that his calculations concerning particular events had proceeded on fallacious data. But what has chiefly rendered his name famous, was his great and fortunate discovery of logarithms in trigonometry, by which the ease and expedition in calculation have so wonderfully assisted the science of astronomy and the arts of practical geometry and navigation. Napier, having a great attachment to astronomy and spherical trigonometry, had occasion to make many numeral calculations of such triangles, with sines, tangents, &c; and these being expressed in large numbers, they hence occasioned a great deal of labour and trouble: to spare themselves part of this labour, Napier, and other authors about his time, set themselves to find out certain short modes of calculation, as is evident from many of their writings. To this necessity, and these endeavours it is, that we owe several ingenious contrivances; particularly the computation by Napier's Rods, and several other curious and short methods that are given in his Rabdologia; and at length, after trials of many other means, the most complete one of logarithms, in the actual construction of a large table of numbers in arithmetical progression, adapted to a set of as many others in geometrical progression. The property of such numbers had been long known, viz, that the addition of the former answered to the multiplication of the latter, &c; but it wanted the necessity of such very troublesome calculations as those above mentioned, joined to an ardent disposition, to make such a use of that property. Perhaps also this disposition was urged into action by certain attempts of this kind which it seems were made elsewhere; such as the following, related by Wood in his Athenæ Oxonienses, under the article Briggs, on the authority of Oughtred and Wingate, viz, "That one Dr. Craig, a Scotchman, coming out of Denmark into his own country, called upon John Neper baron of Marcheston near Edinburgh, and told him, among other discourses, of a new invention in Denmark (by Longomontanus as 'tis said) to save the tedious multiplication and division in astronomical calculations. Neper was very solicitous to know farther of him concerning this matter, but he could give no other account of it, than that it was by proportionable numbers. Which hint Neper taking, he desired him at his return to call upon him again. Craig, after some weeks had passed, did so, and Neper then showed him a rude draught of that he called Canon Mirabilis Logarithmorum. Which draught, with some alterations, he printed in 1614. It came forthwith into the hands of our author Briggs, and into those of William Oughtred, from whom the relation of this matter came."

Whatever might be the inducement however, Napier published his invention in 1614, under the title of Logarithmorum Canonis Descriptio, &c, containing the description and canon of his logarithms, which are those of the kind that is called hyperbolic. This work coming presently to the hands of Mr. Briggs, then professor of geometry at Gresham-college in London, he immediately gave it the greatest encouragement, teaching the nature of the logarithms in his public lectures, and at the same time recommending a change in the scale of them, by which they might be advantageously altered to the kind which he afterwards computed himself, which are thence called Briggs's Logarithms, and are those now in common use. Mr. Briggs also presently wrote to lord Napier upon this proposed change, and made journeys to Scotland the two following years, to visit Napier, and consult with him on the subject of this alteration, before he set about making it. Briggs, in a letter to archbishop Usher, March 10, 1615, writes thus: "Napier lord of Murkinston hath set my head and hands at work with his new and admirable logarithms. I hope to see him this summer, if it please God; for I never saw a book which pleased me better, and made me more wonder." Briggs accordingly made lord Napier the visit, and staid a month with him.

The following passage, from the Life of Lilly the astrologer, contains a curious account of the meeting of those two illustrious men. "I will acquaint you (says Lilly) with one memorable story related unto me by John Marr, an excellent mathematician and geometrician, whom I conceive you remember. He was servant to King James and Charles the First. At first when the lord Napier, or Marchiston, made public his logarithms, Mr. Briggs, then reader of the astronomy lectures at Gresham-college in London, was so surprised with admiration of them, that he could have no quietness in himself until he had seen that noble person the lord Marchiston, whose only invention they were: he acquaints John Marr herewith, who went into Scotland before Mr. Briggs, purposely to be there when those two so learned persons should meet. Mr. Briggs appoints a certain day when to meet at Edinburgh; but failing thereof, the lord Napier was doubtful he would not come. It happened one day as John Marr and the lord Napier were speaking of Mr. Briggs; 'Ah, John (said Marchiston), Mr. Briggs will not now come.' At the very instant one knocks at the gate; John Marr hastens down, and it proved Mr. Briggs to his great contentment. He brings Mr. Briggs up into my lord's chamber, where almost one quarter of an hour was spent, each beholding other almost with admiration before one word was spoke. At last Mr. Briggs began: 'My lord, I have undertaken this long journey purposely to see your person, and to know by what engine of wit or ingenuity you came first to think of this most excellent help into astronomy, viz, the logarithms; but, my lord, being by you found out, I wonder nobody else found it out before, when now known it is so easy.' He was nobly entertained by the lord Napier; and every summer after that, during the lord's being alive, this venerable man Mr. Briggs went purposely into Scotland to visit him."

Napier made also considerable improvements in spherical trigonometry &c, particularly by his Catholic or Universal Rule, being a general theorem by which he resolves all the cases of right-angled spherical triangles in a manner very simple, and easy to be remembered, namely, by what he calls the Five Circular Parts. His Construction of Logarithms too, besides the labour of them, manifests the greatest ingenuity. Kepler dedicated his Ephemerides to Napier, which were published in the year 1617; and it appears from many passages in his letter about this time, that he accounted Napier to be the greatest man of his age in the particular department to which he applied his abilities.

The last literary exertion of this eminent person was the publication of his Rabdology and Promptuary, in the year 1617; soon after which he died at Marchiston, the 3d of April in the same year, and in the 68th year of his age.—The list of his works is as follows:

1. A Plain Discovery of the Revelation of St. John; 1593.

2. Logarithmorum Canonis Descriptio; 1614.

3. Mirifici Logarithmorum Canonis Constructio; &c. Quibus accessere propositiones ad triangula sphærica faciliore calculo resolvenda. Una cum Annotationibus aliquot doctissimi D. Henrici Briggii in eas, et memoratam appendicem. Published by the author's son in 1619.

4. Rabdologia, seu Numerationis per Virgulas, libri duo; 1617. This contains the description and use of the bones or rods; with several other short and ingenious modes of calculation.

5. His Letter to Anthony Bacon (the original of which is in the archbishop's library at Lambeth), entitled, Secret Inventions, Profitable and Necessary in these days for the Defence of this Island, and withstanding Strangers Enemies to God's Truth and Religion; dated June 2, 1596.

NAPIER'S *Bones*, or *Rods*, an instrument contrived by Lord Napier, for the more easy performing of the arithmetical operations of multiplication, division, &c. These rods are five in number, made of bone, ivory, horn, wood, or pasteboard, &c. Their faces are divided into nine little squares (fig. 7, pl. 20); each of which is parted into two triangles by diagonals. In these little squares are written the numbers of the multiplication-table; in such a manner that the units, or right-hand figures, are found in the right-hand triangle; and the tens, or the left-hand figures, in the left-hand triangle; as in the figure.

To Multiply Numbers by NAPIER'S *Bones*. Dispose the rods in such a manner, as that the top figures may exhibit the multiplicand; and to these, on the left-hand, join the rod of units: in which seek the right-hand figure of the multiplier; and take out the numbers corresponding to it, in the squares of the other rods, by adding the several numbers occurring in the same rhomb together, and their sums. After the same manner write out the numbers corresponding to the other figures of the multiplier; disposing them under one another as in the common multiplication; and lastly add the several numbers into one sum. For example, suppose the multiplicand 5978, and the multiplier 937. From the outermost triangle on the right-hand (fig. 8, pl. 20) which corresponds to the right-hand figure of the multiplier 7, take out the figure 6, placing it under the line. In the next rhomb towards the left,

```
   5978
    937
  -----
  41846
 17934
53802
-------
5601386
```

add 9 and 5; their sum being 14, write the right-hand figure 4, against 6; carrying the left-hand figure 1 to 4 and 3, which are found in the next rhomb; and join the sum 8 to 46, already set down. After the same manner, in the last rhomb, add 6 and 5, and the latter figure of the sum 11, set down as before, and carry 1 to the 3 found in the left-hand triangle; the sum 4 join as before on the left-hand of 1846. Thus you will have 41846 for the product of 5978 by 7. And in the same manner are to be found the products for the other figures of the multiplier; after which the whole is to be added together as usual.

To perform Division by NAPIER's *Bones.* Dispose the rods so, that the uppermost figures may exhibit the divisor; to these on the left-hand, join the rod of units. Descend under the divisor, till you meet those figures of the dividend in which it is first required how oft the divisor is found, or at least the next less number, which is to be subtracted from the dividend; then the number corresponding to this, in the place of units, set down for a quotient. And by determining the other parts of the quotient after the same manner, the division will be completed.

```
5978 ) 5601386 ( 937
       53802
       -----
        22118
        17934
        -----
         41846
         41846
```

For example; suppose the dividend 5601386, and the divisor 5978; since it is first inquired how often 5978 is found in 56013, descend under the divisor (fig. 8) till in the lowest series you find the number 53802, approaching nearest to 56013; the former of which is to be subtracted from the latter, and the figure 9 corresponding to it in the rod of units set down for the quotient. To the remainder 2211 join the following figure 8 of the dividend; and the number 17934 being found as before for the next less number to it, the corresponding number 3 in the rod of units is to be set down for the next figure of the quotient. After the same manner the third and last figure of the quotient will be found to be 7; and the whole quotient 937.

NATURAL *Day, Year, &c.* See DAY, YEAR, &c.

NATURAL *Horizon*, is the sensible or physical horizon.

NATURAL *Magic*, is that which only makes use of natural causes; such as the treatise of J. Bapt. Porta, Magia Naturalia.

NATURAL *Philosophy*, otherwise called *Physics*, is that science which considers the powers of nature, the properties of natural bodies, and their actions on one another.

Laws of NATURE, are certain axioms, or general rules, of motion and rest, observed by natural bodies in their actions on one another. Of these laws, Sir I. Newton has established the three following.

1st LAW.—That every body perseveres in the same state, either of rest, or uniform rectilinear motion; unless it is compelled to change that state by the action of some foreign force or agent. Thus, projectiles persevere in their motions, except so far as they are retarded by the resistance of the air, and the action of gravity: and thus a top, once set in motion, only ceases to turn round, because it is resisted by the air, and by the friction of the plane upon which it moves. Thus also the larger bodies of the planets and comets preserve their progressive and circular motions a long time undiminished, in regions void of all sensible resistance.—As body is passive in receiving its motion, and the direction of its motion, so it retains them, or perseveres in them, without any change, till it be acted on by something external.

2d LAW.—The motion, or change of motion, is always proportional to the moving force by which it is produced, and in the direction of the right line in which that force is impressed. If a given force produce a certain motion, a double force will produce double the motion, a triple force triple the motion, and so on. And this motion, since it is always directed to the same point with the generating force, if the body were in motion before, is either to be added to it, as when the motions conspire: or subtracted from it, as when they are opposite; or combined obliquely, when oblique: being always compounded with it according to the determination of each.

3d LAW.—Re-action is always contrary, and equal to action; or the actions of two bodies upon each other, are always mutually equal, and directed contrary ways; and are to be estimated always in the same right line. Thus, if one body press or draw another, it is equally pressed or drawn by it. So, if I press a stone with my finger, the finger is equally pressed by the stone: if a horse draw a weight forward by a rope, the horse is equally opposed or drawn back towards the weight; the equal tension or stretch of the rope hindering the progress of the one, as it promotes that of the other. Again, if any body, by striking on another, do in any manner change its motion, it will itself, by means of the other, undergo also an equal change in its own motion, on account of the equality of the pressure. When two bodies meet, each endeavours to persevere in its state, and resists any change: and because the change which is produced in either may be equally measured by the action which it excites upon the other, or by the resistance which it meets with from it, it follows that the changes produced in the motions of each are equal, but are made in contrary directions: the one acquires no new force but what the other loses in the same direction; nor does this last lose any force but what the other acquires; and hence, though by their collisions, motion passes from the one to the other, yet the sum of their motions, estimated in a given direction, is preserved the same, and is unalterable by their mutual actions upon each other. In these actions the changes are equal; not those, we mean, of the velocities, but those of the motions, or momentums; the bodies being supposed free from any other impediments. For the changes of velocities, which are likewise made contrary ways, inasmuch as the motions are equally changed, are reciprocally proportional to the bodies or masses.—The same law obtains also in attractions.

NAVIGATION, is the art of conducting a ship at sea from one port or place to another. This is perhaps the most useful of all arts, and is of the highest antiquity. It is impossible to say who were the inventors of it; but it is probable that many people cultivated it, independent of each other, who inhabited the sea coasts, and had occasion, or found it convenient, to convey themselves upon the water from place to place; beginning from rafts and logs of wood, and gradually improving in the structure and management of their vessels, according to the length of time and extent of their voyages. Writers however ascribe the invention of this art to different persons, or nations, according to the different sources of their information. Thus,

The poets refer the invention of navigation to Neptune, some to Bacchus, others to Hercules, to Jason, or to

Janus, who it is said made the first ship. Historians ascribe it to the Æginetes, the Phœnicians, Tyrians, and the ancient inhabitants of Britain. Some are of opinion that the first hint was taken from the flight of the kite; and some, as Oppian (De Piscibus, lib. 1), from the fish called Nautilus; while some ascribe it to accident; and others again deriving the hint and invention from Noah's ark.

However, history represents the Phœnicians, especially those of the capital Tyre, as the first navigators that made any extensive progress in the art, so far as has come to our knowledge; and indeed it must have been this very art that made their city what it was. For this purpose, Lebanon, and the other neighbouring mountains, furnishing them with excellent wood for ship-building, they were speedily masters of a numerous fleet, with which constantly hazarding new navigations, and settling new trades, they soon arrived at a high pitch of opulence and population; so as to be in a condition to send out colonies, the principal of which was that of Carthage; which, keeping up their Phœnician spirit of commerce, in time far surpassed Tyre itself; sending their merchant-ships through Hercules's pillars, now the straits of Gibraltar, and thence along the western coasts of Africa and Europe; and even, according to some authors, to America itself. The city of Tyre being destroyed by Alexander the Great, its navigation and commerce were transferred by the conqueror to Alexandria, a new city, well situated for these purposes, and proposed for the capital of the empire of Asia, the conquest of which Alexander then meditated. And thus arose the navigation of the Egyptians; which was afterwards so cultivated by the Ptolemies, that Tyre and Carthage were quite forgotten.

Egypt being reduced to a Roman province after the battle of Actium, its trade and navigation fell into the hands of Augustus: in whose time Alexandria was only inferior to Rome; and the magazines of the capital of the world were wholly supplied with merchandises from the capital of Egyyt.

At length, Alexandria itself underwent the fate of Tyre and Carthage; being surprised by the Saracens, who, in spite of the Emperor Heraclius, overspread the northern coasts of Africa, &c; and the merchants being driven thence, Alexandria has ever since been in a languishing state, though still it has a considerable part of the commerce of the Christian merchants trading to the Levant.

The fall of Rome and its empire drew along with it, not only that of learning and the polite arts, but that of navigation also; the barbarians, into whose hands it fell, contenting themselves with the spoils of the industry of their predecessors.

But no sooner were the brave among those nations well settled in their new provinces; some in Gaul, as the Franks; others in Spain, as the Goths; and others in Italy, as the Lombards; than they began to learn the advantages of navigation and commerce, with the methods of managing them, from the people they subdued; and this with so much success, that in a little time some of them became able to give new lessons, and set on foot new institutions for its advantage. Thus it is to the Lombards we usually ascribe the invention and use of banks, bookkeeping, exchanges, rechanges, &c.

It does not appear which of the European nations, after the settlement of their new masters, first engaged in navigation and commerce.—Some think it began with the French; though the Italians seem to have the juster title to it, and are usually considered as the restorers of both, as well as of the polite arts, which had been banished together from the time the empire was torn asunder. It is the people of Italy then, and particularly those of Venice and Genoa, who have the glory of this restoration; and it is to their advantageous situation for navigation that they in a great measure owe their glory. From about the time of the 6th century, when the inhabitants of the islands in the bottom of the Adriatic began to unite together, and by their union to form the Venetian state, their fleets of merchantmen were sent to all the parts of the Mediterranean; and at last to those of Egypt, particularly Cairo, a new city, built by the Saracen princes on the eastern banks of the Nile, where they traded for their spices and other products of the Indies. Thus they flourished, and increased their commerce, their navigation, and their conquests on the terra firma, till the league of Cambray in 1508, when a number of jealous princes conspired to their ruin; which was the more easily effected by the diminution of their East-India commerce, of which the Portuguese had got one part, and the French another. Genoa too, which had cultivated navigation at the same time with Venice, and that with equal success, was a long time its dangerous rival, disputed with it the empire of the sea, and shared with it the trade of Egypt, and other parts both of the east and west.

Jealousy soon began to break out; and the two republics coming to blows, there was almost continual war for three centuries, before the superiority was ascertained; when, towards the end of the 14th century, the battle of Chioza ended the strife: the Genoese, who till then had usually the advantage, having now lost all; and the Venetians, almost become desperate, at one happy blow, beyond all expectation, secured to themselves the empire of the sea, and the superiority in commerce.

About the same time that navigation was retrieved in the southern parts of Europe, a new society of merchants was formed in the North, which not only carried commerce to the greatest perfection it was capable of, till the discovery of the East and West Indies, but also formed a new scheme of laws for the regulation of it, which still obtain under the name of, Uses and Customs of the Sea. This society is that celebrated league of the Hanse-Towns, which was begun about the year 1164.

The art of navigation has been greatly improved in modern times, both in respect to the form of the vessels themselves, and the methods of working or conducting them. The use of rowers is now entirely superseded by the improvements made in the sails, rigging, &c. The ancients were neither so well skilled in finding the latitudes, nor in steering their vessels in places of difficult navigation, as the moderns. But the greatest advantage which these have over the ancients, is from the mariner's compass, by which they are enabled to find their way with as much facility in the midst of an immeasurable ocean, as the ancients could have done by creeping along the coast, and never going out of sight of land. Some people indeed contend, that this is no new invention, but that the ancients were acquainted with it. They say, it was impossible for Solomon's ships to go to Ophir, Tarshish, and Parvaim, which last they will have to be Peru, without this useful instrument. They insist, that it was impossible for the ancients to be acquainted with the attractive virtue of the magnet, without knowing its polarity. They even affirm, that this property of the magnet is plainly mentioned in the Book of Job, where the loadstone is called topaz, or the stone that turns itself. But, not to mention that Mr. Bruce has lately made it appear highly probable that Solomon's ships made no more than coasting voyages, it is certain that the Romans, who conquered Judea, were ignorant of this instrument; and it is very probable, that so useful an invention, if once it had been commonly known to a nation, would never have been forgotten, or perfectly concealed from so enterprising a people as the Romans, who were so much interested in the discovery of it.

Among those who do agree that the mariner's compass is a modern invention, it has been much disputed who was the inventor. Some give the honour of it to Flavio Gioia of Amalfi in Campania, about the beginning of the 14th century; while others say that it came from the East, and was earlier known in Europe. But, at whatever time it was invented, it is certain, that the mariner's compass was not commonly used in navigation before the year 1420. In that year, the science was considerably improved under the auspices of Henry duke of Visco, brother to the king of Portugal. In the year 1485, Roderic and Joseph, physicians to king John the 2d of Portugal, together with one Martin de Bohemia, a Portuguese native of the island of Fayal, and pupil to Regiomontanus, calculated tables of the sun's declination for the use of sailors, and recommended the astrolabe for taking observations at sea. The celebrated Columbus, it is said, availed himself of Martin's instructions, and improved the Spaniards in the knowledge of this art; for the farther progress of which, a lecture was afterwards founded at Seville by the emperor Charles the 5th.

The discovery of the variation of the compass, is claimed by Columbus, and by Sebastian Cabot. The former certainly did observe this variation without having heard of it from any other person, on the 14th of September 1492, and it is very probable that Cabot might do the same. At that time it was found that there was no variation at the Azores, for which reason some geographers made that the first meridian, though it has since been discovered that the variation alters in time. The use of the cross-staff now began to be introduced among sailors. This ancient instrument is described by John Werner of Nuremberg, in his annotations on the first book of Ptolemy's Geography, printed in 1514: he recommends it for observing the distance between the moon and some star, from which to determine the longitude.

At this time the art of navigation was very imperfect, from the use of the plane chart, which was the only one then known, and which, by its gross errors, must have greatly misled the mariner, especially in places far distant from the equator; and also from the want of books of instruction for seamen.

At length two Spanish treatises appeared on this subject, the one by Pedro de Medina, in 1545; and the other by Martin Cortes, or Curtis as it is printed in English, in 1556, though the author says he composed it at Cadiz in 1545, containing a complete system of the art as far as it was then known. Medina, in his dedication to Philip prince of Spain, laments that multitudes of ships daily perished at sea, because there were neither teachers of the art, nor books by which it might be learned; and Cortes, in his dedication, boasts to the emperor, that he was the first who had reduced navigation into a compendium, valuing himself much on what he had performed. Medina defended the plane chart; but he was opposed by Cortes, who showed its errors, and endeavoured to account for the variation of the compass, by supposing the needle was influenced by a magnetic pole, different from that of the world, and which he called the Point Attractive: which notion has been further prosecuted by others. Medina's book was soon translated into Italian, French, and Flemish, and served for a long time as a guide to foreign navigators. However, Cortes was the favourite author of the English nation, and was translated in 1561, by Richard Eden, while Medina's work was much neglected, though translated also within a short time of the other. At that time a system of navigation consisted of materials such as the following. An account of the Ptolemaic hypothesis, and the circles of the sphere; of the roundness of the earth, the longitudes, latitudes, climates, &c, and eclipses of the luminaries; a calendar; the method of finding the prime, epact, moon's age, and tides; a description of the compass, an account of its variation, for the discovering of which Cortes said an instrument might easily be contrived; tables of the sun's declination for 4 years, in order to find the latitude from his meridian altitude; directions to find the same by certain stars; of the course of the sun and moon; the length of the days; of time and its divisions; the method of finding the hour of the day and night; and lastly, a description of the sea-chart, on which to discover where the ship is; they made use also of a small table, that showed, on an alteration of one degree of the latitude, how many leagues were run on each rhumb, together with the departure from the meridian; which might be called a table of distance and departure, as we have now a table of difference of latitude and departure. Besides, some instruments were described, especially by Cortes; one of which was for finding the place and declination of the sun, with the age and place of the moon; certain dials, the astrolabe, and cross-staff; with a complex machine to discover the hour and latitude at once.

About the same time proposals were made for finding the longitude by observations of the moon. In 1530, Gemma Frisius advised the keeping of the time by means of small clocks or watches, then newly invented, as he says. He also contrived a new kind of cross-staff, and an instrument called the Nautical Quadrant; which last was much praised by William Cuningham, in his Cosmographical Glass, printed in the year 1559.

In the year 1537 Pedro Nunez, or Nonius, published a book in the Portuguese language, to explain a difficulty in navigation, proposed to him by the commander Don Martin Alphonso de Susa. In this work he exposes the errors of the plane chart, and gives the solution of several curious astronomical problems; among which, is that of determining the latitude from two observations of the sun's altitude and the intermediate azimuth being given. He observed, that though the rhumbs are spiral lines, yet the direct course of a ship will always be in the arch of a great circle, by which the angle with the meridians will continually change: all that the steersman can here do for preserving the original rhumb, is to correct these deviations as soon as they appear sensible. But thus the ship will in reality describe a course without the rhumb-line intended; and therefore his calculations for assigning the latitude, where any rhumb-line crosses the several meridians, will be in some measure erroneous. He invented a method of dividing a quadrant by means of concentric circles, which, after being much improved by Dr. Halley, is used at present, and is called a Nonius.

In 1577, Mr. William Bourne published a treatise of navigation, in which, by considering the irregularities in the moon's motion, he shows the errors of the sailors in finding her age by the epact, and also in determining the hour from observing on what point of the compass the sun and moon appeared. In sailing towards high latitudes, he advises to keep the reckoning by the globe, as the plane chart is most erroneous in such situations. He despairs of our ever being able to find the longitude, unless the variation of the compass should be occasioned by some such attractive point as Cortes had imagined; of which however he doubts: but as he had shown how to find the variation at all times, he advises to keep an account of the observations, as useful for finding the place of the ship; which advice was prosecuted at large by Simon Stevin in a treatise published at Leyden in 1599; the substance of which was the same year printed at London in English by Mr. Edward Wright, entitled the Haven-finding Art. In the same old tract also is decribed the method by which our sailors estimate the rate of a ship in her course, by the instrument called the Log. The author of this contrivance is not known; neither was it farther noticed till 1607, when it is mentioned in an East-India voyage published by Purchas: but from this time it became common, and is mentioned by all authors on navigation; and it still continues to be used as at first, though many attempts have been made to improve it, and contrivances proposed to supply its place; some of which have succeeded in still water, but proved useless in a stormy sea.

In 1581 Michael Coignet, a native of Antwerp, published a treatise, in which he animadverted on Medina. In this he showed, that as the rhumbs are spirals, making endless revolutions about the poles, numerous errors must arise from their being represented by straight lines on the sea-charts; but though he hoped to find a remedy for these errors, he was of opinion that the proposals of Nonius were scarcely practicable, and therefore in a great measure useless. In treating of the sun's declination, he took notice of the gradual decrease in the obliquity of the ecliptic; he also described the cross-staff with three transverse pieces, as it was then in common use among the sailors. He likewise gave some instruments of his own invention; but all of them are now laid aside, excepting perhaps his Nocturnal. He constructed a sea-table, to be used by such as sailed beyond the 60th degree of latitude; and at the end of the book is delivered a method of sailing on a parallel of latitude, by means of a ring-dial and a 24-hour-glass.

In the same year Mr. Robert Norman published his Discovery of the Dipping-needle, in a pamphlet called the New Attractive; to which is always subjoined Mr. William Burrough's Discourse of the Variation of the Compass.—In 1594, Captain John Davis published a small treatise, entitled The Seaman's Secrets, which was much esteemed in its time.

The writers of this period complained much of the errors of the plane chart, which continued still in use, though they were unable to discover a proper remedy: till Gerrard Mercator contrived his Universal Map, which he published in 1569, without clearly understanding the principles of its construction; these were first discovered by Mr. Edward Wright, who sent an account of the true method of dividing the meridian from Cambridge, where he was a fellow, to Mr. Blundeville, with a short table for that purpose, and a specimen of a chart so divided. These were published by Blundeville in 1594, among his Exercises; to the later editions of which was added his Discourse on Universal Maps, first printed in 1589. However, in 1599 Mr. Wright printed his Correction of certain Errors in Navigation, in which work he shows the reason of this division, the manner of constructing his table, and its uses in navigation. A second edition of this treatise, with further improvements, was printed in 1610, and a third edition by Mr. Moxon, in 1657.—The method of approximation, by what is called the middle latitude, now used by our sailors, occurs in Gunter's Works, first printed in 1623.—About this time logarithms began to be introduced, which were applied to navigation in a variety of ways by Mr. Edmund Gunter; though the first application of the logarithmic tables to the cases of sailing, was by Mr. Thomas Addison, in his Arithmetical Navigation, printed in 1625.—In 1635 Mr. Henry Gellibrand printed a Mathematical Discourse on the Variation of the Magnetical Needle, containing his discovery of the changes to which the variation is subject.—In 1631, Mr. Richard Norwood published an excellent Treatise of Trigonometry, adapted to the invention of logarithms, particularly in applying Napier's general canons; and for the farther improvement of navigation, he undertook the laborious work of measuring a degree of the meridian, for examining the divisions of the log-line. He has given a full and clear account of this operation in his Seaman's Practice, first published in 1637; where he also describes his own excellent method of setting down and perfecting a sea-reckoning, &c. This treatise, and that of trigonometry, were often reprinted, as the principal books for learning scientifically the art of navigation. What he had delivered, especially in the latter of them, concerning this subject, was contracted as a manual for sailors in a very small piece, called his Epitome, which has gone through a great number of editions.—About the year 1645, Mr. Bond published, in Norwood's Epitome, a very great improvement on Wright's method, by a property in his meridian line, by which its divisions are more scientifically assigned than the author was able to effect; which he deduced from this theorem, that these divisions are analogous to the excesses of the logarithmic tangents of half the respective latitudes increased by 45 degrees, above the logarithm of the radius: this he afterwards explained more fully in the 3d edition of Gunter's Works, printed in 1653; and the demonstration of the general theorem was supplied by Mr. James Gregory of Aberdeen, in his Exercitationes Geometricæ, printed at London in 1668, and afterwards by Dr. Halley, in the Philos. Trans. No. 219, as also by Mr. Cotes, No. 388.—In 1700, Mr. Bond, who imagined that he had discovered the longitude, by having discovered the true theory of the magnetic variation, published a general map, on which curve lines were drawn, expressing the paths or places where the magnetic needle had the same variation. The positions of these curves will indeed continually experience alterations; and therefore they should be corrected from time to time, as they have already been for the years 1744, and 1756, by Mr. William Mountaine, and Mr. James Dodson.—The allowances proper to be made for lee-way, are very particularly set down by Mr. John Buckler, and published in a small tract first printed in 1702, entitled a New Compendium of the whole Art of Navigation, written by Mr. William Jones.

As it is now generally agreed that the earth is a spheroid, whose axis or polar diameter is shorter than the equatorial diameter, Dr. Murdoch published a tract in 1741, in which he adapted Wright's, or Mercator's sailing to such a figure; and in the same year Mr. Maclaurin also, in the Philos. Trans. No. 461, for determining the meridional parts of a spheroid; and he has further prosecuted the same speculation in his Fluxions, printed in 1742.

The method of finding the longitude at sea, by the observed distances of the moon from the sun and stars, commonly called the lunar method, was proposed at an early stage in the art of navigation, (viz, in 1514, by John Werner of Nuremberg,) and has now been happily carried into effectual execution by the encouragement of the Board of Longitude, which was established in England in the year 1714, for rewarding any successful endeavours to keep the longitude at sea. In the year 1767, this board published a Nautical Almanac, which has been continued annually ever since, by the advice, and under the direction of the astronomer-royal at Greenwich: this work is purposely adapted to the use of navigators in long voyages, and, among a great many useful articles, it contains tables of the lunar distances accurately computed for every 3 hours in the year, for the purpose of comparing the distance thus known for any time, with the distance observed in an unknown place, from which to compute the longitude of that place. Under the auspices of this Board too, besides giving encouragement to the authors of many useful tables and other works, which would otherwise have been lost, time-keepers have been brought to a great degree of excellence, by Mr. Harrison, Mr. Arnold, and many other persons, which have proved highly advantageous in keeping the time during long voyages at sea, and thence giving the longitude to a good degree of accuracy.

Some of the other principal writers on navigation are, Stevin, before 1600, in his Hydrography; Bartholomew Crescenti, of Rome, in 1607; Willebrord Snell, at Leyden, in 1624, his Tiphys Batavus; Geo. Fournier, at Paris, 1633; John Baptist Riccioli, at Bologna, in 1661; Dechales, in 1674 and 1677; the Sieur Blondel St. Aubin, in 1671 and 1673; M. Dassier, in 1683; M. Sauveur, in 1692; M. John Bouguer, in 1698; F. Pezenas, in 1733 and 1741; and M. Peter Bouguer, who, in 1753, published a very elaborate treatise on this subject, entitled, Nouveau Traité de Navigation; in which he gives a variation compass of his own invention, and attempts to reform the log, as he had before done in the Memoirs of the Academy of Sciences for 1747. He is also very particular in determining the lunations more accurately than by the common methods, and in describing the corrections of the dead reckoning. This book was abridged and improved by M. Lacaille, in 1760. To these may be added the navigation of Don George Juan of Spain, in 1757. And, in our own nation, the several treatises of Messrs. Newhouse, Seller, Hodgson, Atkinson, Harris, Patoun, Hauxley, Wilson, Moore, Nicholson, &c; but, above all, The Elements of Navigation, in 2 vols, by Mr. John Robertson, first printed about the year 1750, and since often re-printed; which is the most complete work of the kind extant; and to which work is prefixed a Dissertation on the Rise and Progress of the modern Art of Navigation, by Dr. James Wilson, containing a very learned and elaborate history of the writings and improvements in this art.

For an account of the several instruments employed for the purposes of navigation, with the methods for the longitude, and the various kinds and methods of navigation, &c, see the respective articles themselves, as also the preface to Robertson's Navigation.

Navigation is either Proper or Common.

Navigation, *Common*, usually called coasting, in which the places are at no great distance from each other, and the ship sails usually in sight of land, and mostly within soundings. In this, little else is required besides an acquaintance with the lands, the compass, and sounding-line; each of which, see in its place.

Navigation, *Proper*, is where the voyage is long, and pursued through the main ocean. And here, besides the requisites in the former case, are also required the use of Mercator's Chart, the azimuth and amplitude compasses, the log-line, and other instruments for celestial observations; as forestaffs, quadrants, and other sectors, &c.

Navigation turns chiefly upon four things; two of which being given or known, the rest are thence easily found out. These four things are, the difference of latitude, difference of longitude, the reckoning or distance run, and the course or rhumb sailed on. The latitudes are easily found, and that with sufficient accuracy: the course and distance are had by the log-line, or dead reckoning, together with the compass. Nor is there any thing wanting to the perfection of navigation, but to determine the longitude. Mathematicians and astronomers for many ages have applied themselves, with great assiduity, to supply this grand desideratum, but not altogether with the success desired, considering the importance of the object, and the magnificent rewards offered by several states to the discoverer. See Longitude.

Sub-Marine Navigation, or the art of sailing under water, is mentioned by Mr. Boyle, as the desideratum of the art of navigation. This, he says, was successfully attempted, by Cornelius Drebbel; several persons who were in the boat breathing freely all the time. See Diving-*Bell*.

Inland Navigation, is that performed by small craft, upon canals, &c, cut through a country.

NAVIGATOR, a person capable of conducting a ship at sea to any place proposed.

NAUTICAL *Chart*, the same as Sea-Chart.

Nautical *Compass*, the same as Sea-Compass.

Nautical *Planisphere*, a projection or construction of the terrestrial globe on a plane, for the use of mariners; such as the plane chart, and Mercator's chart.

NEAP, or Neep-*Tides*, are those that happen at equal distances between the spring tides. The neap tides are the lowest, as the spring tides are the highest ones, being the opposites to them. And as the highest of the spring tides happens about 3 days after the full or change of the moon, so the lowest of the neap tides fall about 3 days after the quarters, or 4 days before the full and change; when the seamen say it is deep neap.

NEAPED. When a ship wants water, so that she cannot get out of the harbour, out of the dock, or off the ground, they say, she is neaped, or beneaped.

NEBULÆ, or Nebulous, or Cloudy, a term applied to certain fixed stars, which show a dim, hazy light; being less than those of the fith magnitude, and therefore scarcely visible to the naked eye, to which at best they only appear like little dusky specks or clouds.—Through a moderate telescope, most of these nebulous stars plainly appear to be congeries or clusters of several little stars. In the nebulous star called Præsepe, in the breast of Cancer, there are reckoned 36 little stars, 3 of which Mr. Flamsteed sets down in his catalogue. In the nebulous star of Orion, are reckoned 21. F. le Compte adds, that there are 40 in the Pleiades; 12 in the star in the middle of Orion's sword; 500 in the extent of two degrees of the same constellation; and 2500 in the whole constellation. It may further be observed, that the galaxy, or milky-way, is a continued assemblage of nebulæ, or vast clusters of small stars.

Though some of these nebulous spots in the heavens consist of clusters of small stars, others appear as luminous spots of different forms. A remarkable one is in the midway between the two stars on the blade of Orion's sword, marked θ by Bayer, discovered in the year 1656 by Huygens: it contains only 7 stars, and the other part is a bright spot on a dark ground, appearing like an opening into brighter regions beyond.

Dr. Halley and others have discovered nebulæ in several parts of the heavens. In the Connoissance des Temps, for 1783 and 1784, there is a catalogue of 103 nebulæ, observed by Messier and Mechain. But to Dr. Herschel we owe catalogues of 2000 nebulæ, and clusters of stars, discovered by him. Some of these form a round compact system; others are more irregular, and of various forms, some being long and narrow. The globular systems of stars appear thicker in the middle, than they would do if the stars were all at equal distances from each other; they are therefore condensed toward the centre. These he supposes are brought together by their mutual attractions, and that the gradual condensation toward the centre is a proof of a central power of such a kind; and that though the forms are various, it is plain that there is always a tendency to sphericity. And granting that these nebulæ and clusters of stars are formed by mutual attraction, Dr. H. concludes, that we may judge of their relative age by the disposition of their component parts, those being the oldest that are most compressed. He supposes, and indeed offers powerful arguments to prove, that the milky-way is the nebula of which our sun is one of its component parts.

Dr. Herschel has also discovered other phenomena in the heavens, which he calls nebulous stars; that is, stars surrounded by a faint luminous atmosphere of large extent. Those which have been thus styled by other astronomers, he says, ought not to have been so called; for, on examination, they have proved to be either mere clusters of stars plainly to be distinguished by his large telescopes, or such nebulous appearances as might be occasioned by a multitude of stars at a vast distance. The milky-way consists entirely of stars; and he says, "I have been led on by degrees from the most evident congeries of stars, to other groups in which the lucid points were smaller, but still very plainly to be seen; and from them to such in which they could barely be suspected, until I arrived at last to spots in which no trace of a star was to be discovered. But then the gradations to these latter were by such connected steps, as left no room for doubt, but that all these phenomena were equally occasioned by stars variously dispersed in the immense expanse of the universe."

In the same paper is given an account of some nebulous stars, one of which is thus described: "Nov. 13, 1790. A most singular phenomenon! A star of the 8th magnitude, with a faint luminous atmosphere, of a circular form, and of about 3′ in diameter. The star is perfectly in the centre, and the atmosphere is so diluted, faint, and equal throughout, that there can be no surmise of its consisting of stars, nor can there be a doubt of the evident connection between the atmosphere and the star. Another star, not much less in brightness, and in the same field of view with the above, was perfectly free from any such appearance. Hence Dr. H. draws the following consequences: granting the connection between the star and the surrounding nebulosity, if it consist of stars very remote, which gives the nebulous appearance, the central star, which is visible, must be immensely greater than the rest; or if the central star be no larger than common, how extremely small and compressed must be those other luminous points which occasion the nebulosity. As, by the former supposition, the luminous central point must far exceed the standard of what we call a star; so in the latter, the shining matter about the centre will be too small to come under the same denomination; we therefore either have a central body which is not a star, or a star which is involved in a shining fluid, of a nature totally unknown to us." This last opinion Dr. H. adopts.

Light reflected from the star could not be seen at this distance. Besides, the outer parts are nearly as bright as those near the star. Further, a cluster of stars will not so completely account for the mildness or soft tint of the light of these nebulæ, as a self-luminous fluid. What a field of novelty, says Dr. H., is here opened to our conceptions! A shining fluid, of a brightness sufficient to reach us from the regions of a star of the 8th, 9th, 10th, 11th, 12th magnitude; and of an extent so considerable as to take up 3, 4, 5, or 6 minutes in diameter. He conjectures that this shining fluid may be composed of the light perpetually emitted from millions of stars. See Philos. Trans. an. 1791, pa. 1, or my Abridg. vol. 17, pa. 18.

In the vol. for 1811, pa. 269, Dr. Herschel has much farther continued his observations into the nature, construction, and uses of nebulous matter. He shows that it is distributed through the immensity of space, in quantities inconceivably great, and in separate collections of all shapes and sizes, and of all degrees of brightness, between a mere milky appearance and that of a fixed star. He states substantial reasons for conceiving that the whole furniture of the universe is furnished and formed out of collections of it; that it is naturally opaque though self-shining; that by its central gravitation each collection gradually becomes more and more condensed, and more and more rounded in its form; that from the excentricity of its shape, and gravitation, it acquires gradually a rotary motion; that probably this condensation, and roundness, and rotation, go on continually increasing, till the mass come to a hard or firm consistence, and receive all the other characters of a comet or a planet; that by a still further process of condensation, the body becomes a real star self-shining; and that thus, the waste of the celestial bodies, by the perpetual diffusion of their light, is continually compensated and restored, by new formations of such bodies, to replenish for ever the universe with planets and stars!

Dr. H. has again returned to this prolific subject, in a paper communicated to the Royal Society, and read at their meetings Feb. 24, and March 3, 1814. He here relates his observations on the relative magnitudes of the stars, considering those of the first magnitude to be equal to our sun; determined the magnitudes and changes in the appearance of a great number of fixed stars; gave a history of the alterations which he has noticed in the aspect of the sidereal heavens, during the last 30 years; and described those stars which have increased in magnitude or brilliancy, have lost or acquired surrounding nebulæ, or have had wings, or tails, or other peculiarities. He seems of opinion that new sidereal bodies are in a constant and progressive state of formation; that nebulous appearances gradually assume a globular form. He considers the origin and progress of sidereal bodies to be nearly in the following order: first, vague and indistinct nebulæ, like the milky-way; 2d, detached or clustered nebulæ, which consolidate into clusters of stars; 3dly, these stars, becoming more definite, appear with nebulous appendages, in the different forms of wings, tails, &c; and lastly, that all are finally concentrated into one clear, bright, and large star.

NEEDHAM (JOHN TUBERVILLE), a respectable philosopher and catholic divine, was born at London December 10, 1713. His father possessed a considerable patrimony at Hilston, in the county of Monmouth, being of the catholic branch of the Needham family, and who died young, leaving but a small fortune to his four children. Our author, who was the eldest son, studied in the English college of Douai, where he took orders, taught rhetoric for several years, and surpassed all the other professors of that seminary in the knowledge of experimental philosophy.

In 1740, he was engaged by his superiors in the service of the English mission, and was intrusted with the direction of the school erected at Twyford, near Winchester, for the education of the Roman Catholic youth.—In 1744 he was appointed professor of philosophy in the English college at Lisbon, where, on account of his bad health, he remained only 15 months. After his return, he passed several years at London and Paris, which were chiefly employed in microscopical observations, and in other branches of experimental philosophy. The results of these observations and experiments were published in the Philos. Trans. in the year 1749, and in a volume in 12mo at Paris in 1750; and an account of them was also given by M. Buffon, in the first volumes of his natural history. An intimate connection subsisted for a long time between Mr. Needham and this illustrious French naturalist: they made their experiments and observations together; though the results and systems which they deduced from the same objects and operations were totally different.

Mr. Needham was elected a member of the Royal Society of London in the year 1747, and of the Antiquarian Society some time after.—From the year 1751 to 1767 he was chiefly employed in finishing the education of several English and Irish noblemen, by attending them as tutor in their travels through France, Italy, and other countries. He then retired from this wandering life to the English seminary at Paris, and in 1768 was chosen by the Royal Academy of Sciences in that city a corresponding member.

When the regency of the Austrian Netherlands, for the revival of philosophy and literature in that country, formed the project of an Imperial Academy, which was preceded by the erection of a small literary society to prepare the way for its execution, Mr. Needham was invited to Brussels, and was appointed successively chief director of both these foundations; an appointment which he held, together with some ecclesiastical preferments in the Low Countries, till his death, which happened December the 30th 1781.

Mr. Needham's papers inserted in the Philosophical Transactions, were the following, viz;

1. Account of Chalky Tubulous Concretions, called Malm: vol. 42.—2. Microscopical Observations on Worms in Smutty Corn: vol. 42.—3. Electrical Experiments lately made at Paris: vol. 44.—4. Account of M. Buffon's Mirror, which burns at 66 feet: ib.—5. Observations on the Generation, Composition, and Decomposition of Animal and Vegetable Substances: vol. 45.—6. On the Discovery of Asbestos in France: vol 51.

Other works printed at Paris, in French, are,

1. New Microscopical Discoveries: 1745.
2. The same enlarged: 1750.
3. On Microscopical, and the Generation of Organized Bodies: 2 vols, 1769.

NEEDLE, *Magnetical*, denotes a needle, or a slender piece of iron or steel, touched with a loadstone; which, when freely suspended on a pivot or centre, on which it plays, settles at length in a certain direction, either duly, or nearly north-and-south, and called the magnetic meridian. Magnetical needles are of two kinds; horizontal and inclinatory.

Horizontal NEEDLES, are those equally balanced on each side of the pivot which sustains them; and which, playing horizontally, with their two extremes, point out the north and south parts of the horizon.

Construction of a Horizontal NEEDLE. Having procured a thin light piece of pure steel, about 6 inches long, a perforation is made in the middle, over which a brass cap is soldered on, having its inner cavity conical, so as to play freely on the stile or pivot, which has a fine steel point. To give the needle its verticity, or directive faculty, it is rubbed or stroked leisurely on each pole of a magnet, from the south pole towards the north; first beginning with the northern end, and going back at each repeated stroke towards the south: being careful not to give a stroke in a contrary direction, which would counteract the power it had already obtained. Also the hand should not return directly back again the same way it came, but should return in a kind of oval figure, carrying it about 6 or 8 inches beyond the point where the touch ended, but not beyond on the side where the touch begins.

Before touching, the north end of the needle, in our hemisphere, is made a little lighter than the other end; because the touch always destroys an exact balance, and thus causing the needle to dip. And if, after touching, the needle be out of its equilibrium, something must be filed off from the heavier side, till it be found to balance evenly.

Needles may also acquire the magnetic virtue by means of artificial magnetic bars in the following manner: Lay two equal needles parallel, and about an inch asunder, with the north end of one and the south end of the other pointing the same way, and apply two conductors in contact with their ends: then, with two magnetic hard bars, one in each hand, and held as nearly horizontal as can be, with the upper ends, of contrary names, turned outwards to the right and left, let a needle be stroked or rubbed from the middle to both ends at the same time, for ten or twelve times, the north end of a bar going over the south end of a needle, and the south end of a bar going over the north end of a needle: then, without moving from the place, change hands with the bars, or in the same hands turn the other ends downwards, and stroke the other needle in the same manner; so will they both be magnetical. But to make them still stronger, repeat the operation three or four times from needle to needle, and lastly turn the lower side of each needle upwards, and repeat the operations of touching them, as on the former sides.

The needles that were formerly applied to the compass, on board merchant-ships, were formed of two pieces of steel wire, each being bent in the middle, so as to form an obtuse angle, while their ends, being applied together, make an acute one, so that the whole represented the form of a lozenge. Dr. Knight, who has so much improved the compass, found, by repeated experiments, that partly from the foregoing structure, and partly from the unequal hardening of the ends, these needles not only varied from the true direction, but from one another, and from themselves.—Also the needles formerly used on board the men of war, and some of the larger trading vessels, were made of one piece of steel, of a spring temper, and broad towards the ends, but tapering towards the middle. Every needle of this form is found to have six poles instead of two, one at each end, two where it becomes tapering, and two at the hole in the middle.

To remedy these errors and inconveniences, the needle which Dr. Knight contrived for his compass, is a slender parallelopipedon, being quite straight and square at the ends, and so has only two poles; but the curves are a little confused about the hole in the middle, though it is, upon the whole, the simplest and best.—Mr. Michell suggests, that it would be useful to increase the weight and length of magnetic needles, which would render them both more accurate and permanent; also to cover them with a coat of linseed oil, or varnish, to preserve them from rust.—A needle may be prepared occasionally without touching it on a loadstone: for a fine steel sewing-needle, gently laid on the water, or delicately suspended in the air, will take the north-and-south direction.—Thus also a needle heated in the fire, and cooled again in the direction of the meridian, or only in an erect position, acquires the same faculty.

Declination or Variation of the NEEDLE, is the deviation of the horizontal needle from the meridian; or the angle it makes with the meridian, when freely suspended in an horizontal plane. A needle is always changing the line of its direction, traversing slowly to certain limits towards the east and west sides of the meridian. It was at first thought that the magnetic needle pointed due north; but it was observed by Cabot and Columbus that it had a deviation from the north, though they did not suspect that this deviation had itself a variation, and was continually changing. This change in the variation was first observed, according to Bond, by Mr. John Mair, secondly by Mr. Gunter, and thirdly by Mr. Gellibrand, by comparing together the observations made at different times near the same place by Mr. Burrowes, Mr. Gunter, and himself, on which subject he published a discourse in 1635. Soon after this, Mr. Bond ventured to deliver the rate at which the variation changes for several years; by which he foretold that at London in 1657 there would be no variation of the compass, and from that time it would gradually increase the other way, or towards the west, making apparent vibratory motions between certain limits; which happened accordingly: and upon this variation he proposed a method of finding the longitude, which has been further improved by many others since his time, though with very little success. See VARIATION.

The period of the variation, according to Mr. Henry Philips, is only 370 years, but Mr. Bond 600 years, and their yearly motion 36 minutes. The first good observations of the variation were made by Burrowes, about the year 1580, when the variation at London was 11° 15′ east; and since that time the needle has been moving to the westward at that place; also by the observations of different persons, it has been found to point, at different times, as below:

Years.	Observers.		Variat. E. or W.
1580	Burrowes	- -	11° 15′ East.
1622	Gunter	- -	5 56
1634	Gellibrand	- -	4 3
1640	Bond	- -	3 7
1657	Bond	- -	0 0
1665	Bond	- -	1 23 West.
1666	Bond	- -	1 36
1672	-	- -	2 30
1683	-	- -	4 30
1692	-	- -	6 00
1723	Graham	- -	14 17
1747	-	- -	17 40
1774	Royal Society	-	21 16
1775	Royal Society	-	21 43
1776	Royal Society	-	21 47
1777	Royal Society	-	22 12
1778	Royal Society	-	22 20
1779	Royal Society	-	22 28
1780	Royal Society	-	22 41
1804	Royal Society	-	24 10
1805	Royal Society	-	24 8
1806	Royal Society	-	24 9
1807	Royal Society	-	24 10
1808	Royal Society	-	24 12
1812	Royal Society	-	24 16

By this table it appears that, from the first observations in 1580 till 1657, the change in the variation was 11° 15′ in 77 years, which is at the rate nearly of 9′ a year; and from 1657 till 1780, or the space of 123 years, it changed 22° 41′, which is at the rate of 11′ a year nearly; which it may be presumed is very near the truth.

The variation and dip of the needle was for many years carefully observed by the Royal Society while they met at Crane-court; but were discontinued for many years after removing to their new apartments in Somerset-place; though they have lately been there renewed again.

Dipping, or *Inclinatory* NEEDLE, is a needle to show the dip of the magnetic needle, or how far it points below the horizon.

The inclination or dip of the needle was first observed by Robert Norman, a compass-maker at Ratcliffe; and according to him, the dip at that place, in the year 1576, was 71° 50′; and at the Royal Society it was observed for some years lately as follows:

viz. in 1776	-	72° 30′
1778	-	72 25
1780	-	72 17
1805	-	70 25
1808	-	70 1.

Mr. Henry Bond makes the variation and dip of the needle depend on the same motion of the magnetic poles in their revolution, and upon it he founded a method of discovering the longitude at sea.

NEGATIVE, in Algebra, something marked with the sign −, or minus, as being contrary to such as are positive, or marked with the sign plus, +; as negative powers and roots, negative quantities, &c. See Power, Root, Quantity, &c.

Negative *Sign*, the sign of subtraction −, or that which denotes something in defect. Stifel is the first author I find who used this mark − for subtraction, or negation; before his time, the word minus itself was used, or else its initial *m*.

The use of the negative sign in algebra, is attended with several consequences which at first sight are not admitted without some difficulty, and has sometimes given occasion to notions that seem to have no real foundation. This sign implies, that the real value of the quantity represented by the letter to which it is prefixed, is to be subtracted; and it serves, with the positive sign, to keep in view what elements or parts enter into the composition of quantities, and in what manner, whether as increments or decrements, that is whether by addition or subtraction, which is of great use in algebra.

Hence it serves to express a quantity of an opposite quality to a positive; such as a line in a contrary position, a motion with opposite direction, or a centrifugal force in opposition to gravity; and thus it often saves the trouble of distinguishing, and demonstrating separately, the various cases of proportions, and preserves their analogy in view. But as the proportions of lines depend on their magnitude only, without regard to their position; and motions and forces are said to be equal or unequal, in any given ratio, without regard to their directions; and in general the proportion of quantities relates to their magnitude only, without determining whether they are to be considered as increments or decrements; so there is no ground to imagine any other proportion of $+a$ and $-b$, than that of the real magnitudes of the quantities represented by a and b, whether these quantities are, in any particular case, to be added or subtracted.

As to the usual arithmetical operations of addition, subtraction, &c, the case is different, as the effect of the negative sign is here to be carefully attended to, and is to be considered always as producing, in those operations, an effect directly opposite to the positive sign. Thus, it is the same thing to subtract a decrement, as to add an equal increment, or to subtract $-b$ from $a-b$, is to add $+b$ to it: and because multiplying a quantity by a negative number, implies only a repeated subtraction of it, the multiplying $-b$ by $-n$, is subtracting $-b$ as often as there are units in n, and is therefore equivalent to adding $+b$ so many times, or the same as adding $+nb$. But if we infer from this, that 1 is to $-n$ as $-b$ to nb, according to the rule, that unit is to one of the factors as the other factor is to the product, there is not ground to imagine that there is any mystery in this, or any other meaning than that the real quantities represented by 1, n, b, and nb are proportional. For that rule relates only to the magnitude of the factors and product, without determining whether any factor, or the product, is additive or subtractive. But this must be determined in algebraic computations; and this is the proper use concerning the signs, without which the operation could not proceed. Because a quantity to be subtracted is never produced, in composition, by any repeated addition of a positive, or repeated subtraction of a negative, a negative square number is never produced by composition from a root. Hence the $\sqrt{-1}$, or the square root of a negative, implies an imaginary quantity, and in resolution is a mark or character of the impossible cases of a problem, unless it is compensated by another imaginary symbol or supposition, for then the whole expression may have a real signification. Thus $1+\sqrt{-1}$, and $1-\sqrt{-1}$, taken separately, are both imaginary, but yet their sum is the number 2: as the conditions that separately would render the solution of a problem impossible, in some cases destroy each other's effect when conjoined. In the pursuit of general conclusions, and of simple forms for representing them, expressions of this kind must sometimes arise, where the imaginary symbol is compensated in a manner that is not always so obvious. By proper substitutions, however, the expression may be transformed into another, wherein each particular term may have a real signification, as well as the whole expression.

The theorems that are sometimes briefly discovered by the use of this symbol, may be demonstrated without it by the inverse operation, or some other way; and though such symbols are of great use in the computations in the method of fluxions, trigonometry, &c, their evidence cannot be said to depend upon any arts of this kind. See Maclaurin's Fluxions, book 2, chap. 1; Maseres's Use of the Negative Sign, Ludlam's Algebra, and Carnot's Geometrie de Position.

For the rules or ways of using the negative sign in the several rules of algebra, see those rules severally, viz, Addition, Subtraction, Multiplication, &c. And for the method of managing the roots of negative quantities, see Impossibles.

NEIL (William), an ingenious mathematician, son of Sir Paul Neil, usher of the privy chamber to King Charles 1, and was grandson of Dr. Rd. Neil, archbishop of York. He was born Dec. 7, 1637, and was educated at Oxford, in Wadham-college, under Dr. Wilkins; by whose instructions, and those of Dr. Seth Ward, he greatly improved his genius in mathematics. His success in that study appeared as early as 1657, at 19 years of age, when he, first of any one, accurately rectified a curve line, the semicubical parabola, as was testified by the letters of Dr. Wallis, Lord Viscount Brouncker, and Sir Chr. Wren, printed in the Philos. Trans. an. 1673, and my Abridg. vol. 2, pa. 112.—Mr. Neil became an early member of the Royal Society, of which he was elected a fellow in 1663. And his Theory of Motion was communicated to the society in 1669. But the further expectations, which had been conceived of his genius in mathematical and philosophical subjects, were disappointed by his early death, which happened 1670, in the 33d year of his age.

NEWTON (Dr. John), an eminent English mathematician and divine, was the grandson of John Newton of Axmouth in Devonshire, and son of Humphrey Newton of Oundle in Northamptonshire, where he was born in 1622. After receiving the proper foundation of a grammatical education, he was sent to Oxford, where he was entered a commoner of St. Edmund's-hall in 1637. He took the degree of bachelor of arts in 1641; and the year following he was created master, in precedence to many students of quality, on account of his distinguished talents in the great branches of literature. His genius leading him strongly to astronomy and mathematics, he applied himself diligently to those sciences, as well as to divinity, and made a great proficiency in them, which he found of some service to him during Cromwell's government.

After the restoration of Charles the 2d, he reaped the fruits of his loyalty: being created doctor of divinity at Oxford, Sept. 1661, he was made one of the king's chaplains, and rector of Ross in Herefordshire, instead of Mr. John Toombes, ejected for nonconformity. He held this living till his death, which happened at Ross on Christmas day 1678, at 56 years of age.

Mr. Wood gave him the character of a capricious and humorsome person. However that be, his writings are a proof of his great application to study, and a sufficient monument of his genius and skill in the mathematical sciences. These are,

1. Institutio Mathematica: 1654, in 12mo.
2. Tabulæ Mathematicæ: 1654, in 12mo.
3. Astronomia Britannica, &c: 1656, in 4to.
4. Help to Calculation; with Tables of Declination, &c: 1657, 4to.
5. Trigonometria Britannica, in 2 books; the one composed by our author, and the other translated from the Latin of Henry Gellibrand: 1658, folio.
6. Chiliades Centum Logarithmorum, printed with,
7. Geometrical Trigonometry: 1659.
8. Mathematical Elements, 3 parts: 1660, 4to.
9. A Perpetual Diary, or Almanac: 1662.
10. On the Use of the Carpenter's Rule: 1667.
11. Ephemerides, showing the interest and rate of money at 6 per cent. &c: 1667.
12. Chiliades Centum Logarithmorum et Tabula Partium Proportionalium: 1667.
13. The Rule of Interest, or the Case of Decimal Fractions, &c, part 2: 1668, 8vo.
14. School-pastimes for young children, &c: 1669, 8vo.
15. Art of Practical Gauging, &c: 1669.
16. Introduction to the art of Rhetoric: 1671.
17. The Art of Natural Arithmetic in Whole Numbers, and Fractions Vulgar and Decimal: 1671, 8vo.
18. The English Academy: 1677, 8vo.
19. Cosmography.
20. Introduction to Astronomy.
21. Introduction to Geography: 1678, 8vo.

NEWTON (*Sir* ISAAC), one of the greatest philosophers and mathematicians the world has produced, was born at Woolstrop in Lincolnshire on Christmas day 1642. He was descended from the eldest branch of the family of Sir John Newton, Bart. who were lords of the manor of Woolstrop, and had been possessed of the estate for about two centuries before; to which they had removed from Westley in the same county, but originally they came from the town of Newton in Lancashire. Other accounts say, I think more truly, that he was the only child of Mr. John Newton of Colesworth, near Grantham in Lincolnshire, who had there an estate of about 120*l.* a year, which he kept in his own hands. His mother was of the ancient and opulent family of the Ayscoughs, or Askews, of the same county. Our author losing his father while he was very young, the care of his education devolved on his mother, who, though she married again after his father's death, did not neglect to improve by a liberal education the promising genius that was observed in her son. At 12 years of age, by the advice of his maternal uncle, he was sent to the grammar school at Grantham, where he made a good proficiency in the languages, and laid the foundation of his future studies. Even here was observed in him a strong inclination to figures and philosophical subjects. One trait of this early disposition is told of him: he had then a rude method of measuring the force of the wind blowing against him, by observing how much farther he could leap in the direction of the wind, or blowing on his back, than he could leap the contrary way, or opposed to the wind: an early mark of his original infantine genius.

After a few years spent here, his mother took him home; intending, as she had no other child, to have the pleasure of his company; and that, after the manner of his father before him, he should occupy his own estate. But instead of attending to the markets, or the business of the farm, he was occupied in studying and poring over his books, even by stealth, from his mother's knowledge. On one of these occasions his uncle discovered him one day in a hay-loft at Grantham, whither he had been sent to the market, working a mathematical problem; and having otherwise observed the boy's mind to be uncommonly bent upon learning, he prevailed upon his sister to part with him; and he was accordingly sent, in 1660, to Trinity-college, in Cambridge, where his uncle, having himself been a member of it, had still many friends. Isaac was here noticed by Dr. Barrow, who was soon after appointed the first Lucasian professor of mathematics; and observing his bright genius, contracted a great friendship for him. At his outsetting here, Euclid was first put into his hands, as usual, but that author was soon dismissed; our author's genius and application soon rendering him master of the Elements: and as the analytical method of Descartes was then much in vogue, he particularly applied to it, and Kepler's Optics, &c, making several improvements on them, which he entered on the margins of the books as he went on, as his custom was in studying any author.

Thus he was employed till the year 1664, when he opened a way into his new method of Fluxions and Infinite Series; and the same year took the degree of bachelor of arts. In the mean time, observing that the mathematicians were much engaged in the business of improving telescopes, by grinding glasses into one of the figures made by the three sections of a cone, on the principle then generally entertained, that light was homogeneous, he set himself to grinding of optic glasses, of other figures than spherical, having as yet no distrust of the homogeneous nature of light: but not hitting presently on any thing in this attempt to satisfy his mind, he procured a glass prism, that he might try the celebrated phenomena of colours, discovered by Grimaldi not long before. He was much pleased at first with the vivid brightness of the colours produced by this experiment; but after a while, considering them in a philosophical way, with that circumspection which was natural to him, he was surprised to see them in an oblong form, which, according to the received rule of refractions, ought to be circular. At first he thought the irregularity might possibly be no more than accidental;

but this was what he could not leave without further inquiry: accordingly, he soon invented an infallible method of deciding the question; and the result was, his New Theory of Light and Colours.

However, the theory alone, unexpected and surprising as it was, did not satisfy him; he rather considered the proper use that might be made of it for improving telescopes, which was his first design. To this end, having now discovered that light was not homogeneous, but an heterogeneous mixture of differently refrangible rays, he computed the errors arising from this different refrangibility; and, finding them to exceed some hundreds of times those occasioned by the circular figure of the glasses, he threw aside his glass works, and took reflections into consideration. He was now sensible that optical instruments might be brought to any degree of perfection desired, in case there could be found a reflecting substance which would polish as finely as glass, and reflect as much light as glass transmits, and the art of giving it a parabolical figure be also attained: but these seemed to him very great difficulties; nay, he almost thought them insuperable, when he further considered, that every irregularity in a reflecting superficies makes the rays deviate 5 or 6 times more from their due course, than the like irregularities in a refracting one.

Amidst these speculations, he was forced from Cambridge, in 1666, by the plague; and it was more than two years before he made any further progress in the subject. However, he was far from passing his time idly in the country; on the contrary, it was here, at this time, that he first started the hint that gave rise to the system of the world, which is the main subject of the Principia. In his retirement, he was sitting alone in a garden, when some apples falling from a tree, led his thoughts upon the subject of gravity; and, reflecting on the power of that principle, he began to consider, that, as this power is not found to be sensibly diminished at the remotest distance from the centre of the earth to which we can rise, neither at the tops of the loftiest buildings, nor on the summits of the highest mountains, it appeared to him reasonable to conclude, that this power must extend much farther than is usually thought. "Why not as high as the moon?" said he to himself; "and if so, her motion must be influenced by it; perhaps she is retained in her orbit by it: however, though the power of gravity is not sensibly weakened in the little change of distance at which we can place ourselves from the centre of the earth, yet it is very possible that, at the height of the moon, this power may differ in strength much from what it is here." To make an estimate what might be the degree of this diminution, he considered, that if the moon be retained in her orbit by the force of gravity, no doubt the primary planets are carried about the sun by the like power; and, by comparing the periods of the several planets with their distances from the sun, he found, that if any power like gravity held them in their courses, its strength must decrease in the duplicate proportion of the increase of distance. This he concluded, by supposing them to move in perfect circles, concentric to the sun, from which the orbits of the greatest part of them do not much differ. Supposing therefore the force of gravity, when extended to the moon, to decrease in the same manner, he computed whether that force would be sufficient to keep the moon in her orbit.

In this computation, being absent from books, he took the common estimate in use among the geographers and our seamen, before Norwood had measured the earth, namely, that 60 miles make one degree of latitude; but as that is a very erroneous supposition, each degree containing about $69\frac{1}{11}$ of our English miles, his computation upon it did not make the power of gravity, decreasing in a duplicate proportion to the distance, answerable to the power which retained the moon in her orbit: whence he concluded, that some other cause must at least join with the action of the power of gravity on the moon. For this reason he laid aside, for that time, any further thoughts on the matter. Mr. Whiston (in his Memoirs, pa. 33) says, he told him that he thought Descartes's vortices might concur with the action of gravity.

Nor did he resume this inquiry on his return to Cambridge, which was shortly after. The truth is, his thoughts were now engaged on his newly projected reflecting telescope, of which he made a small specimen, with a metallic reflector spherically concave. It was but a rude essay, chiefly defective from the want of a good polish for the metal; which instrument is now in the possession of the Royal Society. In 1667 he was chosen fellow of his college, and took the degree of master of arts. And in 1669, Dr. Barrow resigned to him the mathematical chair at Cambridge, the business of which appointment interrupted for a while his attention to the telescope: however, as his thoughts had been for some time chiefly employed upon optics, he made his discoveries in that science the subject of his lectures, for the first three years after he was appointed mathematical professor; and having now brought his Theory of Light and Colours to a considerable degree of perfection, and having been elected a fellow of the Royal Society in Jan. 1672, he communicated it to that body, to have their judgment upon it; and it was afterwards published in their Transactions, viz, of Feb. 19, 1672. This publication occasioned a dispute upon the truth of it, which gave him so much uneasiness, that he resolved not to publish any thing further for a while on the subject; and in that resolution, he laid up his Optical Lectures, though he had prepared them for the press. And the Analysis by Infinite Series, which he had intended to subjoin to them, unhappily for the world, underwent the same fate, and for the same reason.

In this temper he resumed his telescope; and observing that there was no absolute necessity for the parabolic figure of the glasses, since, if metals could be ground truly spherical, they would be able to bear as great apertures as men could give a polish to, he completed another instrument of the same kind. This answering the purpose so well, as, though only half a foot in length, to show the planet Jupiter distinctly round, with his four satellites, and also Venus horned, he sent it to the Royal Society, at their request, together with a description of it, with further particulars; which were published in the Philosophical Transactions for March 1672. Several attempts were also made by that society to bring it to perfection; but, for want of a proper composition of metal, and a good polish, nothing succeeded, and the invention lay dormant, till Hadley made his Newtonian telescope in 1723. At the request of Leibnitz, in 1676, he explained his invention of Infinite Series, and took notice how far he had improved it by his Method of Fluxions, which however he still concealed, and particularly on this occasion, by a transposition of the letters that make up the two fundamental propositions of it, into an alphabetical order; the letters concerning which are inserted in Collins's Commercium Epistolicum, printed 1712. In the winter between the years 1676 and 1677, he discovered the grand proposition, that, by a centripetal force acting reciprocally as the square of the distance, a planet must revolve in an ellipsis, about the centre of force placed in its lower focus, and, by a radius drawn to that centre, describe areas proportional to the times. In 1680 he made several astronomical observations on the comet that then appeared; which, for some considerable time, he took not to be one and the same, but two different comets; and on this occasion several letters passed between him and Mr. Flamsteed.

He was still under this mistake, when he received a letter from Dr. Hooke, explaining the nature of the line described by a falling body, supposed to be moved circularly by the diurnal motion of the earth, and perpendicularly by the power of gravity. This letter put him on inquiring anew what was the real figure in which such a body moved; and that inquiry, convincing him of another mistake which he had before fallen into concerning that figure, put him upon resuming his former thoughts with regard to the moon; and Picart having not long before, viz, in 1679, measured a degree of the earth with sufficient accuracy, by using his measures, that planet appeared to be retained in her orbit by the sole power of gravity; and consequently that this power decreases in the duplicate ratio of the distance; as he had formerly conjectured. On this principle, he found the line described by a falling body to be an ellipsis, having one focus in the centre of the earth. And finding by this means, that the primary planets really moved in such orbits as Kepler had supposed, he had the satisfaction to see that this inquiry, which he had undertaken at first out of mere curiosity, could be applied to the greatest purposes. Hereupon he drew up about a dozen propositions, relating to the motion of the primary planets round the sun, which were communicated to the Royal Society in the latter end of 1683. Becoming thus known to Dr. Halley, that gentleman, who had attempted the demonstration in vain, applied, in August 1684, to Newton, who assured him that he had absolutely completed the proof. This was also registered in the books of the Royal Society; at whose earnest solicitation Newton finished the work, which was printed under the care of Dr. Halley, and came out about midsummer 1687, under the title of, Philosophiæ Naturalis Principia Mathematica, containing in the third book, the Cometic Astronomy, which had been lately discovered by him, and now made its first appearance in the world: a work which may be considered as the production of a celestial intelligence, rather than of a man.

This work however, in which the great author has built a new system of natural philosophy on the most sublime geometry, did not meet at first with all the applause it deserved, and which it was destined one day to receive. Two reasons concurred in producing this effect: Descartes had then got full possession of the opinion of the scientific world. His philosophy was indeed the creature of a fine imagination, gaily dressed out: he had given her likewise some of nature's fine features, and painted the rest to a seeming likeness of her. On the other hand, Newton had with an unparalleled penetration, and force of genius, pursued nature up to her most secret abode, and was intent to demonstrate her residence to others, rather than anxious to describe particularly the way by which he arrived at it himself: he finished his piece in that elegant conciseness, which had justly gained the ancients universal esteem. In fact, the consequences flow with such rapidity from the principles, that the reader is often left to supply a long chain of reasoning to connect them: so that it required some time before the world could understand it. The best mathematicians were obliged to study it with care, before they could make themselves master of it; and those of a lower rank durst not venture upon it, till encouraged by the testimonies of the more learned. But at last, when its value became sufficiently known, the approbation which had been so slowly gained, became universal, and nothing was to be heard from all quarters, but one general burst of admiration. "Does Mr. Newton eat, drink, or sleep like other men?" says the marquis de l'Hospital, (one of the greatest mathematicians of the age,) to the English who visited him. "I represent him to myself as a celestial genius entirely disengaged from matter."

In the midst of these profound mathematical researches, just before his Principia went to the press in 1686, the privileges of the university being attacked by James the 2d, Newton appeared among its most strenuous defenders, and was on that occasion appointed one of their delegates to the high-commission court; where they made such a defence, that James thought proper to drop the affair. Our author was also chosen one of their members for the Convention-Parliament in 1688, in which he sat till it was dissolved.

Newton's merit was well known to Mr. Montague, then chancellor of the exchequer, and afterwards earl of Halifax, who had been educated at the same college with him; and when he undertook the great work of recoining the money, he fixed his eye upon Newton for an assistant in it; and accordingly, in 1696, he was appointed warden of the mint, in which employment, he rendered very signal service to the nation. And three years after he was promoted to be master of the mint, a place worth 12 or 15 hundred pounds per annum, which he held till his death. On this promotion, he appointed Mr. Whiston his deputy in the mathematical professorship at Cambridge, giving him the full profits of the place, which appointment itself he also procured for him in 1703. The same year our author was chosen president of the Royal Society, a situation which he held till his death, having then presided over it for 25 years; he had also been chosen a member of the Royal Academy of Sciences at Paris in 1699, as soon as the new regulation was made for admitting foreigners into that society.

From the first discovery of the heterogeneous mixture of light, and the production of colours thence arising, he had employed a great part of his time in bringing the experiment, on which the theory is founded, to a degree of exactness that might satisfy himself. The truth is, this seems to have been his favourite invention; 30 years he had spent in this arduous task, before he published it in 1704. In infinite series and fluxions, and in the power and rule of gravity in preserving the solar system, there had been some, though distant hints, given by others before him: whereas in dissecting a ray of light into its primary constituent particles, which then admitted of no further separation; in the discovery of the different refrangibility of these particles thus separated; and that these constituent rays had each its own peculiar colour inherent in it; that rays falling in the same angle of incidence have alternate fits of reflection and refraction; that bodies are rendered transparent by the minuteness of their pores, and become opaque by having them large; and that the most transparent body, by having an extreme thinness, will become less pervious to the light: in all these, which make up his new theory of light and colours, he was absolutely and entirely the first inventor; and as the subject is of the most subtle and delicate nature, he thought it necessary to be himself the last finisher of it.

In fact, the affair that chiefly employed his researches for so many years, was far from being confined to the subject of light alone. On the contrary, all that we know of natural bodies, seemed to be comprehended in it; he had found out, that there was a natural action at a distance between light and other bodies, by which both the reflections and refractions, as well as inflections, of the former, were constantly produced. To ascertain the force and extent of this principle of action, was what had all along engaged his thoughts, and what after all, by its extreme subtlety, escaped his most penetrating spirit. However, though he has not made so full a discovery of this principle, which directs the course of light, as he has in regard to the power by which the planets are kept in their courses; yet he gave the best possible directions for such as should be disposed to carry on the work, and furnished matter abundantly sufficient to animate them to the pursuit. He has indeed hereby opened a way of passing from optics to an entire system of physics; and, if we consider his queries as containing the history of a great man's first thoughts, even in that view they must be always at least entertaining and curious.

This same year, and in the same book with his Optics, he published, for the first time, his Method of Fluxions. It has been already observed, that these two inventions were intended for the public so long before as 1672; but were laid by then, in order to prevent his being engaged on that account in a dispute about them. And it is not a little remarkable, that even now this last piece proved the occasion of another dispute, which continued for many years. Ever since 1684, Leibnitz seems to have claimed the honour of having first invented this method.—Newton saw his design from the beginning, and had sufficiently obviated it in the first edition of the Principia, in 1687 (viz, in the Scholium to the 2d lemma of the 2d book): and with the same view, when he now published that method, he took occasion to acquaint the world, that he invented it in the years 1665 and 1666. In the Acta Eruditorum of Leipsic, where an account is given of this book, the author of that account ascribed the invention to Leibnitz, intimating that Newton borrowed it from him. Dr. Keill, the astronomical professor at Oxford, undertook Newton's defence; and after several answers on both sides, Leibnitz complaining to the Royal Society, this body appointed a committee of their members to examine the merits of the case. These, after considering all the papers and letters relating to the point in controversy, decided in favour of Newton and Keill; as is related at large in the life of this last-mentioned gentleman; and these papers themselves were published in 1712, under the title of Commercium Epistolicum Johannis Collins, 8vo.

In 1705, the honour of knighthood was conferred upon our author by queen Anne, in consideration of his great merit. And in 1714 he was applied to by the House of Commons, for his opinion on a new method of discovering the longitude at sea by signals, which had been laid before them by Ditton and Whiston, in order to procure their encouragement; but the petition was thrown aside on reading Newton's paper delivered to the committee.

The following year, 1715, Leibnitz, with the view of bringing the world more easily into the belief that Newton had taken the method of fluxions from his differential method, attempted to foil his mathematical skill by the famous problem of the trajectories, which he therefore proposed to the English by way of challenge; but the solution of this, though the most difficult proposition he was able to devise, and what might pass for an arduous affair to any other, yet was hardly any more than an amusement to Newton's penetrating genius: he received the problem at 4 o'clock in the afternoon, as he was returning from the Mint; and, though extremely fatigued with business, yet he finished the solution before he went to bed.

As Leibnitz was privy-counsellor of justice to the elector of Hanover, so when that prince was raised to the British throne, Newton came more under the notice of the court; and it was for the immediate satisfaction of George the First, that he was prevailed on to put the last hand to the dispute about the invention of fluxions. In this court, Caroline princess of Wales, afterwards queen-consort to George the Second, happened to have a curiosity for philosophical inquiries; no sooner therefore was she informed of our author's attachment to the house of Hanover, than she engaged his conversation, which soon endeared him to her. Here she found in every difficulty that full satisfaction, which she had in vain sought for elsewhere; and she was often heard to declare publicly, that she thought herself happy in coming into the world at a juncture of time, which put it in her power to converse with him. It was at this princess's solicitation, that he drew up an abstract of his Chronology; a copy of which was at her request communicated, about 1718, to signior Conti, a Venetian nobleman, then in England, on a promise to keep it secret. But notwithstanding this promise, the abbé, (who, while here, had also affected to show a particular friendship for Newton, though privately betraying him as much as lay in his power to Leibnitz,) was no sooner got across the water into France, than he dispersed copies of it, and procured an antiquary to translate it into French, as well as to write a confutation of it. This, being printed at Paris in 1725, was delivered as a present from the bookseller that printed it to our author, that he might obtain, as was said, his consent to the publication; but though he expressly refused such consent, yet the whole was published the same year. Hereupon Newton found it necessary to publish a Defence of himself, which was inserted in the Philosophical Transactions. Thus he, who had so much all his life long been studious to avoid disputes, was unavoidably all his lifetime, in a manner, involved in them; nor did this last dispute even finish at his death, which happened the year following. Newton's paper was republished in 1726 at Paris, in French, with a letter of the abbé Conti in answer to it; and the same year some dissertations were printed there by father Souciet against Newton's Chronological Index, an answer to which was inserted by Halley in the Philos. Trans. No. 397.

Some time before this business, in his 80th year, our author was seized with an incontinence of urine, thought to proceed from the stone in the bladder, and deemed to be incurable. However, by the help of a strict regimen and other precautions, which till then he never had occasion for, he procured considerable intervals of ease during the five remaining years of his life. Yet he was not free from some severe paroxysms, which even forced out large drops of sweat that ran down his face. In these circumstances he was never observed to utter the least complaint, nor express the least impatience; and as soon as he had a moment's ease, he would smile and talk with his usual cheerfulness. He was now obliged to rely upon Mr. Conduit, who had married his niece, for the discharge of his office in the mint. Saturday morning March 18, 1727, he read the newspapers, and discoursed a long time with Dr. Mead his physician, having then the perfect use of all his senses and his understanding; but that night he entirely lost them, and did not recover them afterwards; he died the Monday following, March 20, in the 85th year of his age. His corpse lay in state in the Jerusalem-chamber, and on the 28th was conveyed into Westminster-abbey, the pall being supported by the lord-chancellor, the dukes of Montrose and Roxburgh, and the earls of Pembroke, Sussex, and Macclesfield. He was interred near the entrance into the choir on the left hand, where a stately monument is erected to his memory, with a most elegant inscription upon it.

Newton's character has been attempted by M. Fontenelle and Dr. Pemberton, the substance of which is as follows. He was of a middle stature, and somewhat inclined to be fat in the latter part of his life. His countenance was pleasing and venerable at the same time; especially when he took off his peruke and showed his white hair, which was pretty thick. He never made use of spectacles, and lost but one tooth during his whole life. Bishop Atterbury says, that, in the whole air of Sir Isaac's face and make, there was nothing of that penetrating sagacity which appears in his compositions: that he had something rather languid in his look and manner, which did not raise any great expectation in those who did not know him.

His temper it is said was so equal and mild, that no accident could disturb it. A remarkable instance of which is related as follows. Sir Isaac had a favourite little dog, which he called Diamond. Being one day called out of his study into the next room, Diamond was left behind. When Sir Isaac returned, having been absent but a few minutes, he had the mortification to find, that Diamond having overset a lighted candle among some papers, the nearly finished labour of many years was in flames, and almost consumed to ashes. This loss, as Sir Isaac was then very far advanced in years, was irretrievable; yet, without once striking the dog, he only rebuked him with this exclamation, "Oh Diamond! Diamond! thou little knowest the mischief thou hast done!" Dr. Wallis (Algeb. p. 347) says, some papers on series and curves were ready for the press in 1671, but by mischance were burnt.

Newton was indeed of so meek and gentle a disposition, and so great a lover of peace, that he would rather have chosen to remain in obscurity, than to have the calm of life ruffled by those storms and disputes, which genius and learning always draw upon those that are most eminent for them.

From his love of peace, no doubt, arose that unusual kind of horror which he felt for all disputes: a steady unbroken attention, free from those frequent recoilings inseparably incident to others, was his peculiar felicity; he knew it, and he knew the value of it. No wonder then that controversy was looked on as his bane. When some objections, hastily made to his discoveries concerning light and colours, induced him to lay aside the design he had taken of publishing his Optical Lectures, we find him reflecting on that dispute, into which he had been unavoidably drawn, in these terms: "I blamed my own imprudence for parting with so real a blessing as my quiet, to run after a shadow." It is true this shadow, as Fontenelle observes, did not escape him afterwards, nor did it cost him that quiet which he so much valued, but proved as much a real happiness to him as his quiet itself; yet this was a happiness of his own making: he took a resolution from these disputes, not to publish any more concerning that theory, till he had put it above the reach of controversy, by the most exact experiments, and the strictest demonstrations; and accordingly it has never been called in question since. In the same temper, after he had sent the manuscript to the Royal Society, with his consent to the printing of it by them; yet upon Hooke's injuriously insisting that he himself had demonstrated Kepler's problem before our author, he determined, rather than be involved again in controversy, to suppress the third book; and he was very hardly prevailed on to alter that resolution. It is true, the public was thereby a gainer; that book, which is indeed no more than a corollary of some propositions in the first, being originally drawn up in the popular way, with a design to publish it in that form; whereas he was now convinced that it would be best not to let it go abroad without a strict demonstration.

In contemplating Newton's genius, it presently becomes a doubt, which of these endowments had the greatest share, sagacity, penetration, strength, or diligence; and, after all, the mark that seems most to distinguish it is, that he himself made the justest estimation of it, declaring, that if he had done the world any service, it was due to nothing but industry and patient thought; that he kept the subject of consideration constantly before him, and waited till the first dawning opened gradually, by little and little, into a full and clear light. It is said, that when he had any mathematical problems or solutions in his mind, he would never quit the subject on any account. And his servant has said, when he has been getting up in a morning, he has sometimes begun to dress, and with one leg in his breeches, sat down again on the bed, where he has remained for hours before he has got his clothes on: and that dinner has been often three hours ready for him before he could be brought to table.

After all, notwithstanding his anxious care to prevent interruption in his intense application to study, he could nevertheless, when occasion required it, lay aside his thoughts, though engaged in the most intricate researches, when his other affairs required his attention; and, as soon as he had leisure, resume the subject at the point where he had left off. This he seems to have done not so much by any extraordinary strength of memory, as by the force of his inventive faculty, to which every thing opened itself again with ease, if nothing intervened to ruffle him. The readiness of his invention made him not think of putting his memory much to the trial; but this was the offspring of a vigorous intenseness of thought, out of which he was but a common man. He spent therefore the prime of his age in those abstruse researches, when his situation in a college gave him leisure, and while study was his proper business. But as soon as he was removed to the mint, he applied himself chiefly to the duties of that office; and so far quitted mathematics and philosophy, as not to engage in any pursuits of either kind afterwards.

Dr. Pemberton observes, that though his memory was much decayed in the last years of his life, yet he perfectly understood his own writings, contrary to what I had formerly heard, says the doctor, in discourse from many persons. This opinion of theirs might arise perhaps from his not being always ready at speaking on these subjects, when it might be expected he should. But on this head it may be observed, that great geniuses are often liable to be absent, not only in relation to common life, but with regard to some of the parts of science that they are best informed of: inventors seem to treasure up in their minds what they have found out, after another manner than those do the same things who have not this inventive faculty. The former, when they have occasion to produce their knowledge, are in some measure obliged immediately to investigate part of what they want; and for this they are not equally fit at all times: from whence it has often happened, that such as retain things chiefly by means of a very strong memory, have appeared off-hand more expert than the discoverers themselves.

It was evidently owing to the same inventive faculty that Newton, as this writer found, had read fewer of the modern mathematicians than one could have expected; his own prodigious invention readily supplying him with what he might have occasion for in the pursuit of any subject he undertook. However, he often censured the handling of geometrical subjects by algebraic calculations; and his book of algebra he called by the name of Universal Arithmetic, in opposition to the injudicious title of Geometry, which Descartes had given to the treatise in which he shows how the geometrician may assist his invention by such kind of computations. He frequently praised Slusius, Barrow, and Huygens, for not being influenced by the false taste which then began to prevail. He used to commend the laudable attempt of Hugo d'Omerique to restore the ancient analysis; and very much esteemed Apollonius's book De Sectione Rationis, for giving us a clearer notion of that analysis than we had before. Dr. Barrow may be esteemed as having shown a compass of invention equal, if not superior, to any of the moderns, our author only excepted: but Newton particularly recommended Huygens's style and manner: he thought him the most elegant of any mathematical writer of modern times, and the truest imitator of the ancients. Of their taste and mode of demonstration our author always professed himself a great admirer; and even censured himself for not following them yet more closely than he did; and spoke with regret of his mistake at the beginning of his mathematical studies, in applying himself to the works of Descartes, and other algebraic writers, before he had considered the Elements of Euclid with that attention which so excellent a writer deserves.

But if this was a fault, it is certain it was a fault to which we owe both his great inventions in speculative mathematics, and the doctrine of fluxions and infinite series. And perhaps this might be one reason why his particular reverence for the ancients is omitted by Fontenelle, who however certainly makes some amends by that just elogium which he makes of our author's modesty, which amiable quality he represents as standing foremost in the character of this great man's mind and manners. It was in reality greater than can be easily imagined, or will be readily believed: yet it always continued so without any alteration; though the whole world, says Fontenelle, conspired against it; let us add, though he was thereby robbed of his invention of fluxions. Nicholas Mercator publishing his Logarithmotechnia in 1668, where he gave the quadrature of the hyperbola by an infinite series, which was the first appearance in the learned world of a series of this sort drawn from the particular nature of the curve, and that in a manner very new and abstracted; Dr. Barrow, then at Cambridge, where Newton, then about 26 years of age, resided, recollected, that he had met with the same thing in the writings of that young gentleman; and there not confined to the hyperbola only, but extended, by general forms, to all kinds of curves, even such as are mechanical; to their quadratures, their rectifications, and their centres of gravity; to the solids formed by their rotations, and to the superficies of those solids; so that, when their determinations were possible, the series stopped at a certain point, or at least their sums were given by stated rules: and if the absolute determinations were impossible, they could yet be infinitely approximated; which is the happiest and most refined method, says Fontenelle, of supplying the defects of human knowledge that man's imagination could possibly invent. To be master of so fruitful and general a theory was a mine of gold to a geometrician; but it was a greater glory to have been the discoverer of so surprising and ingenious a system. So that Newton, finding by Mercator's book, that he was in the way to it, and that others might follow in his track, should naturally have been forward to open his treasures, and secure the property, which consisted in making the discovery; but he contented himself with his treasure which he had found, without regarding the glory. What an idea does it give us of his unparalleled modesty, when we find him declaring, that he thought Mercator had entirely discovered his secret, or that others would, before he should become of a proper age for writing! His manuscript on infinite series was communicated to none but Mr. John Collins and the lord Brounker, then president of the Royal Society, who had also done something in this way himself; and even that had not been complied with, but for Dr. Barrow, who would not suffer him to indulge his modesty so much as he desired.

It is further observed, concerning this part of his character, that he never talked either of himself or others, nor ever behaved in such a manner, as to give the most malicious censurers the least occasion even to suspect him of vanity. He was candid and affable, and always put himself upon a level with his company. He never thought either his merit or his reputation sufficient to excuse him from any of the common offices of social life. No singularities, either natural or affected, distinguished him from other men. Though he was firmly attached to the church of England, he was averse to the persecution of the nonconformists. He judged of men by their manners; and the true schismatics, in his opinion, were the vicious and the wicked. Not that he confined his principles to natural religion, for it is said he was thoroughly persuaded of the truth of revelation; and amidst the great variety of books which he had constantly before him, that which he studied with the greatest application was the Bible, at least in the latter years of his life: and he understood the nature and force of moral certainty as well as he did that of a strict demonstration.

Sir Isaac did not neglect the opportunities of doing good, when the revenues of his patrimony and a profitable employment, improved by a prudent œconomy, put it in his power. We have two remarkable instances of his bounty and generosity; one to Mr. Maclaurin, extra professor of mathematics at Edinburgh, to encourage whose appointment he offered 20 pounds a-year to that office; and the other to his niece Barton, upon whom he had settled an annuity of 100 pounds per annum. When decency on any occasion required expense and show, he was magnificent without grudging it: at all other times, that pomp which seems great to low minds only, was utterly retrenched, and the expense reserved for better uses.—On this head it may be remarked however, as a curious fact, that by an order of council, dated Jan. 28, 1675, (which was 3 years after his election into the Royal Society,) it was ordered, that he should be excused from making the usual weekly payments (one shilling per week), on account of his low circumstances, as he represented.

Newton never married; and it has been said, that "perhaps he never had leisure to think of it; that, being immersed in profound studies during the prime of his age, and afterwards engaged in an employment of great importance, and even quite taken up with the company which his merit drew to him, he was not sensible of any vacancy in life, nor of the want of a companion at home." These however do not appear to be any sufficient reasons for his never marrying, if he had had an inclination so to do. It is much more likely that he had a constitutional indifference to the state, and even to the sex in general; and it has even been said of him, that he never once knew woman.—He left at his death, it seems, 32 thousand pounds; but he made no will, which, Fontenelle tells us, was because he thought a legacy was no gift.—As to his works, besides what were published in his life-time, there were found after his death, among his papers, several discourses on the subjects of antiquity, history, divinity, chemistry, and mathematics: several of which were published at different times, as appears from the following catalogue of all his works; where they are ranked in the order of time in which those upon the same subject were published.

1. Several Papers relating to his Telescope, and his Theory of Light and Colours, printed in the Philosophical Transactions, Nos. 80, 81, 82, 83, 84, 85, 88, 96, 97, 110, 121, 123, 128; or vols. 6, 7, 8, 9, 10, 11.

2. Optics, or a Treatise of the Reflections, Refractions, and Inflections, and the Colours of Light; 1704, 4to.—A Latin translation by Dr. Clarke; 1706, 4to.—And a French translation by Pet. Coste, Amst. 1729, 2vols 12mo.—Beside several English editions in 8vo.

3. Optical Lectures; 1728, 8vo.—Also in several Letters to Mr. Oldenburg, secretary of the Royal Society, inserted in the General Dictionary, under our author's article.

4. Lectiones Opticæ; 1729, 4to.

5. Naturalis Philosophiæ Principia Mathematica; 1687, 4to.—A second edition in 1713, with a Preface, by Roger Cotes.—The 3d edition in 1726, under the direction of Dr. Pemberton.—An English translation, by Motte, 1729, 2 volumes 8vo, printed in several editions of his works, in different nations, particularly an edition, with a large Commentary, by the two learned Jesuits, Le Seur and Jacquier, in 4 volumes 4to, in 1739, 1740, and 1742.

6. A System of the World, translated from the Latin original; 1727, 8vo.—This, as has been already observed, was at first intended to make the third book of his Principia, an English translation by Motte, 1729, 8vo.

7. Several Letters to Mr. Flamsteed, Dr. Halley, and Mr. Oldenburg.—See our author's article in the General Dictionary.

8. A Paper concerning the Longitude; drawn up by order of the House of Commons; ibid.

9. Abregé de Chronologie, &c; 1726, under the direction of the abbé Conti, together with some observations upon it.

10. Remarks on the Observations made upon a Chronological Index of Sir I. Newton, &c. Philos. Trans. vol. 33. See also the same, vol. 34 and 35, by Dr. Halley.

11. The Chronology of Ancient Kingdoms amended, &c; 1728, 4to.

12. Arithmetica Universalis, &c; under the inspection of Mr. Whiston, Cantab. 1707, and again in 1722, 8vo. Printed I think without the author's consent, and even against his will: an offence which it seems was never forgiven. There are also English editions of the same, particularly one by Wilder, with a Commentary, in 1769, 2 vols 8vo. And a Latin edition, with a Commentary, by Castilion, 2 vols 4to, Amst. &c.

13. Analysis per Quantitatum Series, Fluxiones, et Differentias, cum Enumeratione Linearum Tertii Ordinis; 1711, 4to; under the inspection of W. Jones, Esq. F. R. S.—The last tract had been published before, together with another on the Quadrature of Curves, by the Method of Fluxions, under the title of Tractatus duo de Speciebus et Magnitudine Figurarum Curvilinearum; subjoined to the first edition of his Optics in 1704; and other letters in the Appendix to Dr. Gregory's Catoptrics, &c, 1735, 8vo.—Under this head may be ranked Newtoni Genesis Curvarum per Umbras; Leyden, 1740.

14. Several Letters relating to his Dispute with Leibnitz, on his Right to the Invention of Fluxions; printed in the Commercium Epistolicum D. Johannis Collins et aliorum de Analysi Promota, jussu Societatis Regiæ editum; 1712, 8vo.

15. Postscript and Letter of M. Leibnitz to the Abbé Conti, with Remarks, and a Letter of his own to that Abbé; 1717, 8vo. To which was added, Raphson's History of Fluxions, as a Supplement.

16. The Method of Fluxions, and Analysis by Infinite Series, translated into English from the original Latin; to which is added, a Perpetual Commentary, by the translator Mr. John Colson; 1736, 4to.

17. Several Miscellaneous Pieces, and Letters, as follow:—(1) A Letter to Mr. Boyle on the subject of the Philosopher's Stone. Inserted in the General Dictionary, under the article BOYLE.—(2) A Letter to Mr. Aston, containing directions for his travels; ibid. under our author's article.—(3) An English Translation of a Latin Dissertation on the Sacred Cubit of the Jews. Inserted among the miscellaneous works of Mr. John Greaves, vol. 2, published by Dr. Thomas Birch, in 1737, 2 vols. 8vo. This Dissertation was found subjoined to a work of Sir Isaac's, not finished, entitled Lexicon Propheticum.—(4) Four Letters from Sir Isaac Newton to Dr. Bentley, containing some arguments in proof of a Deity; 1756, 8vo.—(5) Two Letters to Mr. Clarke, &c.

18. Observations on the Prophecies of Daniel and the Apocalypse of St. John; 1733, 4to.

19. Tables for purchasing College Leases; 1742, 12mo.

20. Corollaries, by Whiston.

21. A Collection of several pieces of our author's, under the following title, Newtoni Is. Opuscula Mathematica

Philos. et Philol. collegit J. Castilioneus; Laus. 1744, 4to, 8 tomes.

22. Two Treatises on the Quadrature of Curves, and Analysis by Equations of an Infinite Number of Terms, explained: translated by John Stewart, with a large Commentary; 1745, 4to.

23. Description of an Instrument for observing the Moon's Distance from the Fixed Stars at Sea. Philos. Trans. vol. 42.

24. Newton also published Barrow's Optical Lectures, in 1669, 4to: and Bern. Varenii Geographia, &c; 1681, 8vo.

25. The whole works of Newton, published by Dr. Horsley; 1779, 4to, in 5 volumes.

The following is a list of the papers left by Newton at his death, as mentioned above.

A Catalogue of Sir Isaac Newton's Manuscripts and Papers, as annexed to a Bond, given by Mr. Conduit, to the Administrators of Sir Isaac; by which he obliges himself to account for any profit he shall make by publishing any of the papers.

Dr. Pellet, by agreement of the executors, entered into Acts of the Prerogative Court, being appointed to peruse all the papers, and judge which were proper for the press.

No.

1. Viaticum Nautarum; by Robert Wright.
2. Miscellanea; not in Sir Isaac's hand-writing.
3. Miscellanea; part in Sir Isaac's hand.
4. Trigonometria; about 5 sheets.
5. Definitions.
6. Miscellanea; part in Sir Isaac's hand.
7. 40 sheets in 4to, relating to Church History.
8. 126 sheets written on one side, being foul draughts of the Prophetic Stile.
9. 88 sheets relating to Church History.
10. About 70 loose sheets in small 4to, of Chemical papers; some of which are not in Sir Isaac's hand.
11. About 62 ditto, in folio.
12. About 15 large sheets, doubled into 4to; Chemical.
13. About 8 sheets ditto, written on one side.
14. About 5 sheets of foul papers, relating to Chemistry.
15. 12 half-sheets of ditto.
16. 104 half-sheets, in 4to, ditto.
17. About 22 sheets in 4to, ditto.
18. 24 sheets, in 4to, on the Prophecies.
19. 29 half-sheets; being an answer to Mr. Hooke, on Sir Isaac's Theory of Colours.
20. 87 half-sheets relating to the Optics, some of which are not in Sir Isaac's hand.

From No. 1 to No. 20 examined on the 20th of May 1727, and judged not fit to be printed.

T. Pellet.

Witness, *Tho. Pilkington.*

21. 328 half-sheets in folio, and 63 in small 4to; being loose and foul papers relating to the Revelations and Prophecies.
22. 8 half-sheets in small 4to, relating to Church Matters.
23. 24 half-sheets in small 4to; being a discourse relating to the 2d of Kings.
24. 353 half-sheets in folio, and 57 in small 4to; being foul and loose papers relating to Figures and Mathematics.
25. 201 half-sheets in folio, and 21 in small 4to; loose and foul papers relating to the Commercium Epistolicum.
26. 91 half-sheets in small 4to, in Latin, on the Temple of Solomon.
27. 37 half-sheets in folio, on the Host of Heaven, the Sanctuary, and other Church Matters.
28. 44 half-sheets in folio, on ditto.
29. 25 half-sheets in folio; being a farther account of the Host of Heaven.
30. 51 half-sheets in folio; being an Historical Account of two notable Corruptions of Scripture.
31. 88 half-sheets in small 4to; being Extracts of Church History.
32. 116 half-sheets in folio; being Paradoxical Questions concerning Athanasius, of which several leaves in the beginning are very much damaged.
33. 56 half-sheets in folio, De Motu Corporum; the greatest part not in Sir Isaac's hand.
34. 61 half sheets in small 4to; being various sections on the Apocalypse.
35. 25 half-sheets in folio, of the Working of the Mystery of Iniquity.
36. 20 half-sheets in folio, on the Theology of the Heathens.
37. 24 half-sheets in folio; being an Account of the Contest between the Host of Heaven, and the Transgressors of the Covenant.
38. 31 half-sheets in folio; being Paradoxical Questions concerning Athanasius.
39. 107 quarter-sheets in small 4to, on the Revelations.
40. 74 half-sheets in folio; being loose papers relating to Church History.

May 22, 1727, examined from No. 21 to No. 40 inclusive, and judged them not fit to be printed; only No. 33 and No. 38 should be reconsidered.

T. Pellet.

Witness, *Tho. Pilkington.*

41. 167 half-sheets in folio; being loose and foul papers relating to the Commercium Epistolicum.
42. 21 half-sheets in folio; being the 3d letter on Texts of Scripture, very much damaged.
43. 31 half-sheets in folio; being foul papers relating to Church Matters.
44. 495 half-sheets in folio; being loose and foul papers relating to Calculations and Mathematics.
45. 335 half-sheets in folio; being loose and foul papers relating to the Chronology.
46. 112 sheets in small 4to, relating to the Revelations and other Church Matters.
47. 126 half-sheets in folio; being loose papers relating to the Chronology, part in English and part in Latin.
48. 400 half-sheets in folio; being loose mathematical papers.
49. 109 sheets in 4to, relating to the Prophecies, and Church Matters.
50. 127 half-sheets in folio, relating to the University; great part not in Sir Isaac's hand.
51. 18 sheets in 4to; being Chemical papers.
52. 255 quarter-sheets; being Chemical papers.

53. An Account of Corruptions of Scripture; not in Sir Isaac's hand.
54. 31 quarter-sheets; being Flammell's Explication of Hieroglyphical Figures.
55. About 350 half-sheets; being Miscellaneous papers.
56. 6 half-sheets; being An Account of the Empires, &c, represented by St. John.
57. 9 half-sheets folio, and 71 quarter-sheets 4to; being Mathematical papers.
58. 140 half-sheets, in 9 chapters, and 2 pieces in folio, titled, Concerning the Language of the Prophets.
59. 606 half-sheets folio, relating to the Chronology; 9 more in Latin.
60. 182 half-sheets folio; being loose papers relating to the Chronology and Prophecies.
61. 144 quarter-sheets, and 95 half-sheets folio; being loose Mathematical papers.
62. 137 half-sheets folio; being loose papers relating to the Dispute with Leibnitz.
63. A folio Common-place book; part in Sir Isaac's hand.
64. A bundle of English Letters to Sir Isaac, relating to Mathematics.
65. 54 half-sheets; being loose papers found in the Principia.
66. A bundle of loose Mathematical Papers; not Sir Isaac's.
67. A bundle of French and Latin Letters to Sir Isaac.
68. 136 sheets folio, relating to Optics.
69. 22 half-sheets folio, De Rationibus Motuum, &c; not in Sir Isaac's hand.
70. 70 half-sheets folio; being loose Mathematical Papers.
71. 38 half-sheets folio; being loose papers relating to Optics.
72. 47 half-sheets folio; being loose papers relating to Chronology and Prophecies.
73. 40 half-sheets folio; Processus Mysterii Magni Philosophicus, by Wm. Yworth; not in Sir Isaac's hand.
74. 5 half-sheets; being a Letter from Rizzetto to Martine, in Sir Isaac's hand.
75. 41 half-sheets; being loose papers of several kinds, part in Sir Isaac's hand.
76. 40 half-sheets; being loose papers, foul and dirty, relating to Calculations.
77. 90 half-sheets folio; being loose Mathematical papers.
78. 176 half-sheets folio; being loose papers relating to Chronology.
79. 176 half-sheets folio; being loose papers relating to the Prophecies.
80. { 12 half-sheets folio; An Abstract of the Chronology.
92 half-sheets folio; The Chronology.
81. 40 half-sheets folio; The History of the Prophecies, in 10 chapters, and part of the 11th unfinished.
82. 5 small bound books in 12mo, the greatest part not in Sir Isaac's hand, being rough Calculations.

May 26th 1727, Examined from No. 41 to No. 82 inclusive, and judged not fit to be printed, except No. 80, which is agreed to be printed, and part of No. 61, and 81, which are to be reconsidered.

Th. Pellet.
Witness, *Tho. Pilkington.*

It is astonishing what care and industry Sir Isaac had employed about the papers relating to Chronology, Church History, &c; as, on examining the papers themselves, which are in the possession of the family of the earl of Portsmouth, it appears that many of them are copies over and over again, often with little or no variation; the whole number being upwards of 4000 sheets in folio, or 8 reams of folio paper; besides the bound books &c in this catalogue, of which the number of sheets is not mentioned. Of these there have been published only the Chronology, and Observations on the Prophecies of Daniel and the Apocalypse of St. John.

Many other curious particulars concerning Sir Isaac Newton, may be seen in Mr. Edmund Turnor's Collections relating to the town of Grantham, published in 1806.

NEWTONIAN *Philosophy*, the doctrine of the universe, or the properties, laws, affections, actions, forces, motions, &c, of bodies, both celestial and terrestrial, as delivered by Newton.

This term however is differently applied; which has given occasion to some confused notions relating to it. For some authors, under this term, include all the corpuscular philosophy, considered as it now stands reformed and corrected by the discoveries and improvements made in several parts of it by Newton. In which sense it is, that Gravesande calls his Elements of Physics, Introductio ad Philosophiam Newtonianam. And in this sense the Newtonian is the same as the new philosophy; and stands contradistinguished from the Cartesian, the Peripatetic, and the ancient Corpuscular.

Others, by Newtonian philosophy, mean the method or order used by Newton in philosophising; viz, the reasoning and inferences drawn directly from phenomena, exclusive of all previous hypotheses; the beginning from simple principles, and deducing the first powers and laws of nature from a few select phenomena, and then applying those laws &c to account for other things. In this sense, the Newtonian philosophy is the same with the experimental philosophy, or stands opposed to the ancient corpuscular, and to all hypothetical and fanciful systems.—Others again, by this term, mean that philosophy to which physical bodies are considered mathematically, and where geometry and mechanics are applied to the solution of phenomena. In which sense, the Newtonian is the samo with the mechanical and mathematical philosophy.—Others, by Newtonian philosophy, understand that of physical knowledge which Newton has handled, improved, and demonstrated.—And lastly, others, by this philosophy, mean the new principles which Newton has brought into philosophy; with the new system founded upon them, and the new solutions of phenomena thence deduced; or that which characterizes and distinguishes his philosophy from all others. And this is the sense in which we shall here chiefly consider it.

This philosophy was first published in the year 1687, the author being then professor of mathematics in the university of Cambridge; a 2d edition, with considerable additions and improvements, appeared in 1713; and a 3d in 1726. An edition, with a very large commentary, was published in 1739, by Le Seur and Jacquier; besides the complete edition of all Newton's works, with notes, by

Dr. Horsley, in 1779 &c. Several authors have endeavoured to make it plainer; by setting aside many of the more sublime mathematical researches, and substituting either more obvious reasonings or experiments instead of them; particularly Whiston, in his Prælect. Phys. Mathem.; Gravesande, in Elem. et Inst.; Pemberton, in his View &c; and Maclaurin, in his Account of Newton's Philosophy.

The chief parts of the Newtonian philosophy, as delivered by the author, except his Optical Discoveries &c, are contained in his Principia, or Mathematical Principles of Natural Philosophy. He founds his system on the following definitions. 1. Quantity of Matter, is the measure of the same, arising from its density and bulk conjointly.—Thus, air of a double density, in the same space, is double in quantity; in a double space, is quadruple in quantity; in a triple space, is sextuple in quantity, &c.—2. Quantity of Motion, is the measure of the same, arising from the velocity and quantity of matter conjunctly.—This is evident, because the motion of the whole is the motion of all its parts; and therefore in a body double in quantity, with equal velocity, the Motion is double, &c.—3. The Vis Insita, Vis Inertiæ, or innate force of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether it be of rest, or moving uniformly forward in a right line.—This definition is proved to be just by experience, from observing the difficulty with which any body is moved out of its place, upwards, or obliquely, or even downwards when acted on by a body endeavouring to urge it quicker than the velocity given it by gravity; and any how to change its state of motion or rest. And therefore this force is the same, whether the body have gravity or not; and a cannon-ball, void of gravity, if it could be, being discharged horizontally, will go the same distance in that direction, in the same time, as if it were endued with gravity.—4. An Impressed Force, is an action exerted on a body, in order to change its state, whether of rest or motion.—This force consists in the action only; and remains no longer in the body when the action is over. For a body maintains every new state it acquires, by its vis inertiæ only.—5. A Centripetal Force, is that by which bodies are drawn, impelled, or any way tend towards a point, as to a centre. This may be considered of three kinds, absolute, accelerative, and motive.—6. The Absolute quantity of the centripetal force, is a measure of the same, proportional to the efficacy of the cause that urges it to the centre.—7. The Accelerative quantity of a centripetal force, is the measure of the same, proportional to the velocity which it generates in a given time.—8. The Motive quantity of a centripetal force, is a measure of the same, proportional to the motion which it generates in a given time.—This is always known by the quantity of a force equal and contrary to it, that is just sufficient to hinder the descent of the body.

After these definitions, follow certain Scholia, treating of the nature and distinctions of Time, Space, Place, Motion, Absolute, Relative, Apparent, True, Real, &c. After which, the author proposes to show how we are to collect the true motions from their causes, effects, and apparent differences; and vice versa, how, from the motions, either true or apparent, we may arrive at the knowledge of their causes and effects. In order to this, he lays down the following axioms or laws of motion.

1st Law. Every body perseveres in its state of rest, or of uniform motion in a right line, unless it be compelled to change that state by forces impressed on it.—Thus, "Projectiles persevere in their motions, so far as they are not retarded by the resistance of the air, or impelled downwards by the force of gravity. A top, whose parts, by their cohesion, are perpetually drawn aside from rectilinear motions, does not cease its rotation otherwise than as it is retarded by the air or friction, &c. The greater bodies of the planets and comets, meeting with less resistance in more free spaces, preserve their motions, both progressive and circular, for a much longer time."

2d Law. The Alteration of motion is always proportional to the motive force impressed; and is made in the direction of the right line in which that force is impressed. Thus, if any force generate a certain quantity of motion, a double force will generate a double quantity, whether that force be impressed all at once, or in successive moments.

3d Law. To every action there is always opposed an equal re-action: or the mutual actions of two bodies upon each other, are always equal, and directed to contrary parts. Thus, whatever draws or presses another, is as much drawn or pressed by that other. If you press a stone with your finger, the finger is also pressed by the stone: &c.

From this axiom, or law, Newton deduces the following corollaries.—1. A body by two forces conjoined will describe the diagonal of a parallelogram, in the same time that it would describe the sides by those forces apart.—2. Hence is explained the composition of any one direct force out of any two oblique ones, viz, by making the two oblique forces the sides of a parallelogram, and the diagonal the direct one.—3. The quantity of motion, which is collected by taking the sum of the motions directed towards the same parts, and the difference of those that are directed to contrary parts, suffers no change from the action of bodies among themselves; because the motion which one body loses, is communicated to another.—4. The common centre of gravity of two or more bodies does not alter its state of motion or rest by the actions of the bodies among themselves; and therefore the common centre of gravity of all bodies, acting on each other, (excluding external actions and impediments,) is either at rest, or moves uniformly in a right line.—5. The motions of bodies included in a given space are the same among themselves, whether that space be at rest, or move uniformly forward in a right line without any circular motion. The truth of this is evident from the experiment of a ship; where all motions are just the same, whether the ship be at rest, or proceed uniformly forward in a straight line.—6. If bodies, any how moved among themselves, be urged in the direction of parallel lines by equal accelerative forces, they will all continue to move among themselves, after the same manner as if they had not been urged by such forces.

The mathematical part of the Newtonian Philosophy depends chiefly on the following lemmas; especially the first; containing the doctrine of prime and ultimate ratios.—Lem. 1. Quantities, and the ratios of quantities, which in any finite time converge continually to equality, and before the end of that time approach nearer the one to the other than by any given difference, become ultimately equal.—Lem. 2 shows, that in a space bounded by two right lines and a curve, if an infinite number of parallelograms be inscribed, all of equal breadth; then the ultimate ratio of the curve space and the sum of the parallelograms, will be a ratio of equality.—LEM. 3 shows, that the same thing is true when the breadths of the parallelograms are unequal.

In the succeeding lemmas it is shown, in like manner, that the ultimate ratios of the sine, chord, and tangent of arcs infinitely diminished, are ratios of equality, and therefore that in all our reasonings about these, we may safely use the one for the other:—that the ultimate form of evanescent triangles, made by the arc, chord, or tangent, is that of similitude, and their ultimate ratio is that of equality; and hence, in reasonings about ultimate ratios, these triangles may safely be used one for another, whether they are made with the sine, the arc, or the tangent.—The author then demonstrates some properties of the ordinates of curvilinear figures; and shows that the spaces which a body describes by any finite force urging it, whether that force is determined and immutable, or continually varied, are to each other, in the very beginning of the motion, in the duplicate ratio of the forces:—and lastly, having added some demonstrations concerning the evanescence of angles of contact, he proceeds to lay down the mathematical part of his system, which depends on the following theorems.

THEOR. 1. The areas which revolving bodies describe by radii drawn to an immoveable centre of force, lie in the same immoveable planes, and are proportional to the times in which they are described.—To this prop. are annexed several corollaries, respecting the velocities of bodies revolving by centripetal forces, the directions and proportions of those forces, &c; such as, that the velocity of such a revolving body, is reciprocally as the perpendicular let fall from the centre of force upon the line touching the orbit in the place of the body, &c.

THEOR. 2. Every body that moves in any curve line described in a plane, and, by a radius drawn to a point either immoveable or moving forward with a uniform rectilinear motion, describes about that point areas proportional to the times, is urged by a centripetal force directed to that point.—With corollaries relating to such motions in resisting mediums, and to the direction of the forces when the areas are not proportional to the times.

THEOR. 3. Every body that, by a radius drawn to the centre of another body, any how moved, describes areas about that centre proportional to the times, is urged by a force compounded of the centripetal forces tending to that other body, and of the whole accelerative force by which that other body is impelled.—With several corollaries.

THEOR. 4. The centripetal force of bodies, which by equal motions describe different circles, tend to the centres of the same circles; and are one to the other as the squares of the arcs described in equal times, applied to the radii of the circles.—With many corollaries, relating to the velocities, times, periodic forces, &c. And, in a scholium, the author further adds, Moreover, by means of the foregoing proposition and its corollaries, we may discover the proportion of a centripetal force to any other known force, such as that of gravity. For if a body by means of its gravity revolve in a circle, concentric to the earth, this gravity is the centripetal force of that body.—But from the descent of heavy bodies, the time of one entire revolution, as well as the arc described in any given time, is given by a corol. to this prop. And by such propositions, Mr. Huygens, in his excellent book De Horologio Oscillatorio, has compared the force of gravity with the centrifugal forces of revolving bodies.

On these, and such like principles, depends the Newtonian mathematical philosophy. The author further shows how to find the centre to which the forces impelling any body are directed, having the velocity of the body given: and finds that the centrifugal force is always as the versed sine of the nascent arc directly, and as the square of the time inversely; or directly as the square of the velocity, and inversely as the chord of the nascent arc. From these premises, he deduces the method of finding the centripetal force directed to any given point when the body revolves in a circle; and this, whether the central point be near, or at immense distance; so that all the lines drawn from it may be considered as parallels. And he shows the same thing with regard to bodies revolving in spirals, ellipses, hyperbolas, or parabolas. He shows also, having the figures of the orbits given, how to find the velocities and moving powers; and indeed resolves all the most difficult problems relating to the celestial bodies with a surprising degree of mathematical skill. These problems and demonstrations are all contained in the first book of the Principia: but an account of them here would neither be generally understood, nor easily comprised in the limits of this work.

In the second book, Newton treats of the properties and motion of fluids, and their powers of resistance, with the motion of bodies through such resisting mediums, those resistances being in the ratio of any powers of the velocities; and the motions being either made in right lines or curves, or vibrating like pendulums. And here he demonstrates such principles as entirely overthrow the doctrine of Descartes's vortices, which was the fashionable system in his time; concluding the book with these words: "So that the hypothesis of vortices is utterly irreconcileable with astronomical phenomena, and rather serves to perplex than explain the heavenly motions. How these motions are performed in free spaces without vortices, may be understood by the first book; and I shall now more fully treat of it in the following book Of the System of the World."—In this second book he makes great use of the doctrine of fluxions, then lately invented; for which purpose he lays down the principles of that doctrine in the 2d lemma, in these words: "The moment of any genitum, is equal to the moments of each of the generating sides drawn into the indices of the powers of those sides, and into their coefficients continually:" which rule he demonstrates, and then adds the following scholium concerning the invention of that doctrine: "In a letter of mine," says he, "to Mr. J. Collins, dated December 10, 1672, having described a method of tangents, which I suspected to be the same with Slusius's method, which at that time was not made public; I subjoined these words: 'This is one particular, or rather a corollary, of a general method which extends itself, without any troublesome calculation, not only to the drawing of tangents to any curve lines, whether geometrical or mechanical, or any how respecting right lines or other curves, but also to the resolving other abstruser kinds of problems about the curvature, areas, lengths, centres of gravity of curves, &c; nor is it (as Hudden's method de maximis et minimis) limited to equations which are free from surd quantities. This method I have interwoven with that other of working in equations, by reducing them to infinite series.' So far that letter. And these last words relate to a treatise I composed on that subject in the year 1671." Which, at least, is therefore the date of the invention of the doctrine of fluxions.

On entering upon the 3d book of the Principia, Newton briefly recapitulates the contents of the two former books in these words: "In the preceding books I have laid down the principles of philosophy; principles not philosophical, but mathematical; such, to wit, as we may build our reasonings upon in philosophical inquiries. These principles are, the laws and conditions of certain motions, and powers or forces, which chiefly have respect to philosophy. But lest they should have appeared of themselves dry and barren, I have illustrated them here and there with some philosophical scholiums, giving an account of such things as are of a more general nature, and which philosophy seems chiefly to be founded on; such as the density and the resistance of bodies, spaces void of all matter, and the motion of light and sounds. It remains, he adds, that from the same principles I now demonstrate the frame of the system of the world. Upon this subject, I had indeed composed the 3d book in a popular method, that it might be read by many. But afterwards considering that such as had not sufficiently entered into the principles could not easily discern the strength of the consequences, nor lay aside the prejudices to which they had been many years accustomed; therefore to prevent the disputes which might be raised on such accounts, I chose to reduce the substance of that book into the form of propositions, in the mathematical way, which should be read by those only, who had first made themselves masters of the principles established in the preceding books."

As a necessary preliminary to this 3d part, Newton lays down the following rules for reasoning in natural philosophy:—1. We are to admit no more causes of natural things, than such as are both true and sufficient to explain their natural appearances.—2. Therefore to the same natural effects we must always assign, as far as possible, the same causes.—3. The qualities of bodies which admit neither intension nor remission of degrees, and which are found to belong to all bodies within the reach of our experiments, are to be esteemed the universal qualities of all bodies whatever.—4. In experimental philosophy, we are to consider propositions collected by general induction from phenomena, as accurately or very nearly true, notwithstanding any contrary hypotheses that may be imagined, till such time as other phenomena occur, by which they may either be made more accurate, or liable to exceptions.

The phenomena first considered are, 1. That the satellites of Jupiter, by radii drawn to his centre, describe areas proportional to the times of description; and that their periodic times, the fixed stars being at rest, are in the sesquiduplicate ratio of their distances from that centre. 2. The same thing is likewise observed of the phenomena of Saturn. 3. The five primary planets, Mercury, Venus, Mars, Jupiter, and Saturn, with their several orbits, encompass the sun. 4. The fixed stars being supposed at rest, the periodic times of the said five primary planets, and of the earth, about the sun, are in the sesquiduplicate proportion of their mean distances from the sun. 5. The primary planets, by radii drawn to the earth, describe areas no ways proportional to the times: but the areas which they describe by radii drawn to the sun are proportional to the times of description. 6. The moon, by a radius drawn to the centre of the earth, describes an area proportional to the time of description. All which phenomena are clearly evinced by astronomical observations. The mathematical demonstrations are next applied by Newton in the following propositions.

Prop. 1. The forces by which the satellites of Jupiter are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the centre of that planet; and are reciprocally as the squares of the distances of those satellites from that centre.—Prop. 2. The same thing is true of the primary planets, with respect to the sun's centre.—Prop. 3. The same thing is also true of the moon, in respect of the earth's centre.—Prop. 4. The moon gravitates towards the earth; and by the force of gravity is continually drawn off from a rectilinear motion, and retained in her orbit.—Prop. 5. The same thing is true of all the other planets, both primary and secondary, each with respect to the centre of its motion.—Prop. 6. All bodies gravitate towards every planet; and the weights of bodies towards any one and the same planet, at equal distances from its centre, are proportional to the quantities of matter they contain.—Prop. 7. There is a power of gravity tending to all bodies, proportional to the several quantities of matter which they contain.—Prop. 8. In two spheres mutually gravitating each towards the other, if the matter in places on all sides, round about and equidistant from the centres, be similar; the weight of either sphere towards the other, will be reciprocally as the square of the distance between their centres.—Hence are compared together the weights of bodies towards different planets: hence also are discovered the quantities of matter in the several planets: and hence likewise are found the densities of the planets.—Prop. 9. The force of gravity, in parts downwards from the surface of the planets towards their centres, decreases nearly in the proportion of the distances from those centres.

These, and many other propositions and corollaries, are proved or illustrated by a great variety of experiments, in all the great points of physical astronomy; such as, That the motions of the planets in the heavens may subsist an exceeding long time:—That the centre of the system of the world is immoveable:—That the common centre of gravity of the earth, the sun, and all the planets, is immoveable:—That the sun is agitated by a perpetual motion, but never recedes far from the common centre of gravity of all the planets:—That the planets move in ellipses which have their common focus in the centre of the sun; and, by radii drawn to that centre, they describe areas proportional to the times of description:—The aphelions and nodes of the orbits of the planets are fixt:—To find the aphelions, excentricities, and principal diameters of the orbits of the planets:—That the diurnal motions of the planets are uniform, and that the libration of the moon arises from her diurnal motion:—Of the proportion between the axes of the planets and the diameters perpendicular to those axes:—Of the weights of bodies in the different regions of our earth:—That the equinoctial points go backwards, and that the earth's axis, by a nutation in every annual revolution, twice vibrates towards the ecliptic, and as often returns to its former position:—That all the motions of the moon, and all the inequalities of those motions, follow from the principles above laid down:—Of the unequal motions of the satellites of Jupiter and Saturn:—Of the flux and reflux of the sea, as arising from the actions of the sun and moon:—Of the forces with which the sun disturbs the motions of the moon; of the various motions of the moon, of her orbit, variation, inclinations of her orbit, and the several motions of her nodes:—Of the tides, with the forces of the sun and moon to produce them:—Of the figure of the moon's body:—Of the precession of the equinoxes:—And of the motions and trajectory of comets. The great author then concludes with a general scholium, containing reflections on the principal parts of the great and beautiful system of the universe, and of the infinite, eternal Creator and Governor of it.

"The hypothesis of vortices," says he, "is pressed with many difficulties. That every planet by a radius drawn to the sun may describe areas proportional to the times of description, the periodic times of the several parts of the vortices should observe the duplicate proportion of their distances from the sun. But that the periodic times of the planets may obtain the sesquiduplicate proportion of their distances from the sun, the periodic times of the parts of the vortex ought to be in the sesquiduplicate proportion of their distances. That the smaller vortices may maintain their lesser revolutions about Saturn, Jupiter, and other planets, and swim quietly and undisturbed in the greater vortex of the sun, the periodic times of the parts of the sun's vortex should be equal. But the rotation of the sun and planets about their axes, which ought to correspond with the motions of their vortices, recede far from all these proportions. The motions of the comets are exceeding regular, are governed by the same laws with the motions of the planets, and can by no means be accounted for by the hypothesis of vortices. For comets are carried with very excentric motions through all parts of the heavens indifferently, with a freedom that is incompatible with the notion of a vortex.

"Bodies, projected in our air, suffer no resistance but from the air. Withdraw the air, as is done in Mr. Boyle's vacuum, and the resistance ceases. For in this void a bit of fine down and a piece of solid gold descend with equal velocity. And the parity of reason must take place in the celestial spaces above the earth's atmosphere; in which spaces, where there is no air to resist their motions, all bodies will move with the greatest freedom; and the planets and comets will constantly pursue their revolutions in orbits given in kind and position, according to the laws above explained. But though these bodies may indeed persevere in their orbits by the mere laws of gravity, yet they could by no means have at first derived the regular position of the orbits themselves from those laws.

"The six primary planets are revolved about the sun, in circles concentric with the sun, and with motions directed towards the same parts, and almost in the same plane. Ten moons are revolved about the earth, Jupiter and Saturn, in circles concentric with them, with the same direction of motion, and nearly in the planes of the orbits of those planets. But it is not to be conceived that mere mechanical causes could give birth to so many regular motions: since the comets range over all parts of the heavens, in very excentric orbits. For by that kind of motion they pass easily through the orbs of the planets, and with great rapidity; and in their aphelions, where they move the slowest, and are detained the longest, they recede to the greatest distances from each other, and thence suffer the least disturbance from their mutual attractions. This most beautiful system of the sun, planets, and comets, could only proceed from the counsel and dominion of an intelligent and powerful Being. And if the fixed stars are the centres of other like systems, these being formed by the like wise counsel, must be all subject to the dominion of one; especially, since the light of the fixed stars is of the same nature with the light of the sun, and from every system light passes into all the other systems. And lest the system of the fixed stars should, by their gravity, fall on each other mutually, he hath placed those systems at immense distances one from another."

Then, after a truly pious and philosophical descant on the attributes of the Being who could give existence and continuance to such prodigious mechanism, and with so much beautiful order and regularity, the great author proceeds; "Hitherto we have explained the phenomena of the heavens and of our sea, by the power of gravity, but have not yet assigned the cause of this power. This is certain, that it must proceed from a cause that penetrates to the very centres of the sun and planets, without suffering the least diminution of its force; that it operates, not according to the quantity of the surfaces of the particles upon which it acts (as mechanical causes do), but according to the quantity of the solid matter which they contain, and propagates its virtue on all sides, to immense distances, decreasing always in the duplicate proportion of the distances. Gravitation towards the sun, is made up out of the gravitations towards the several particles of which the body of the sun is composed; and in receding from the sun, decreases accurately in the duplicate proportion of the distances, as far as the orb of Saturn, as evidently appears from the quiescence of the aphelions of the planets; nay, and even to the remotest aphelions of the comets, if those aphelions are also quiescent. But hitherto I have not been able to discover the cause of those properties of gravity from phenomena, and I frame no hypotheses. For whatever is not deduced from the phenomena, is to be called an hypothesis; and hypotheses, whether metaphysical or physical, whether of occult qualities or mechanical, have no place in experimental philosophy. In this philosophy, particular propositions are inferred from the phenomena, and afterwards rendered general by induction. Thus it was that the impenetrability, the mobility, and the impulsive force of bodies, and the laws of motion and of gravitation, were discovered. And to us it is enough, that gravity does really exist, and act according to the laws which we have explained, and abundantly serves to account for all the motions of the celestial bodies, and of our sea.

"And now we might add something concerning a certain most subtle spirit, which pervades and lies hid in all gross bodies, by the force and action of which spirit, the particles of bodies mutually attract one another at near distances, and cohere, if contiguous, and electric bodies operate to greater distances, as well repelling as attracting the neighbouring corpuscles; and light is emitted, reflected, refracted, inflected, and heats bodies; and all sensation is excited, and the members of animal bodies move at the command of the will, namely, by the vibrations of this spirit, mutually propagated along the solid filaments of the nerves, from the outward organs of sense to the brain, and from the brain into the muscles. But these are things that cannot be explained in few words, nor are we furnished with that sufficiency of experiments which is required to an accurate determination and demonstration of the laws by which this electric and elastic spirit operates."

NICHE, a cavity, or hollow part, in the thickness of a wall, to place a figure or statue in.

NICOLE (FRANCIS), a celebrated French mathematician, was born at Paris December the 23d, 1683. His early attachment to the mathematics induced M. Montmort to take the charge of his education; and he opened to him the way to the higher geometry. He first became publicly remarkable by detecting the fallacy of a pretended quadrature of the circle. This quadrature a M. Mathulon so assuredly thought he had discovered, that he deposited, in the hands of a public notary at Lyons, the sum of 3000 livres, to be paid to any person who, in the judgment of the Academy of Sciences, should demonstrate the falsity of his solution. M. Nicole, piqued at this challenge, undertook the task, and exposing the paralogism, the Academy's judgment was, that Nicole had plainly proved that the rectilineal figure which Mathulon had given as equal to the circle, was not only unequal to it, but that it was even greater than the polygon of 32 sides circumscribed about the circle.—The prize of 3000 livres, Nicole presented to the public hospital of Lyons.

The Academy named Nicole, Elève-Mechanician, March 12, 1707; Adjunct in 1716, Associate in 1718, and Pensioner in 1724; which he continued till his death, which happened the 18th of January 1758, at 75 years of age.

His works were all inserted in the different volumes of the Memoirs of the Academy of Sciences; and are as follow:

1. A General Method for determining the Nature of Curves formed by the Rolling of other Curves upon any Given Curve; in the volume for the year 1707.—2. A General Method for Rectifying all Roulets upon Right and Circular Bases; 1708.—3. General Method of determining the Nature of those Curves, which cut an Infinity of other Curves given in Position, cutting them always in a Constant Angle; 1715.—4. Solution of a Problem proposed by M. de Lagny; 1716.—5. Treatise of the Calculus of Finite Differences; 1717.—6. Second Part of the Calculus of Finite Differences; 1723.—7. Second Section of ditto; 1723.—8. Addition to the two foregoing papers; 1724.—9. New Proposition in Elementary Geometry; 1725.—10. New Solution of a Problem proposed to the English Mathematicians, by the late M. Leibnitz; 1725.—11. Method of Summing an Infinity of New Series, which are not summable by any other known method; 1727.—12. Treatise of the Lines of the Third Order, or the Curves of the Second Kind; 1729.—13. Examination and Resolution of some Questions relating to Play; 1730.—14. Method of determining the Chances at Play.—15. Observations on the Conic Sections; 1731.—16. Manner of generating, in a Solid Body, all the Lines of the Third Order; 1731.—17. Manner of determining the Nature of Roulets formed on the Convex Surface of a Sphere; and of determining which are Geometric, and which are Rectifiable; 1732.—18. Solution of a Problem in Geometry; 1732.—19. The Use of Series in resolving many Problems in the Inverse Method of Tangents; 1737.—20. Observations on the Irreducible Case in Cubic Equations; 1738.—21. Observations on Cubic Equations; 1738.—22. On the Trisection of an Angle; 1740.—23. On the Irreducible Case in Cubic Equations; 1741.—24. Addition to ditto; 1743.—25. His Last Paper on the same; 1744.—26. Determination, by Incommensurables and Decimals, the Values of the Sides and Areas of the Series in a Double Progression of Regular Polygons, inscribed in and circumscribed about a Circle; 1747.

NICOMEDES, an ancient mathematician, who flourished in the 2d century of the Christian æra, and was celebrated for his invention of the curve called the Conchoid.

NIEUWENTYT (BERNARD), an eminent Dutch philosopher and mathematician, was born on the 10th of August 1654, at Westgraafdyk in North Holland, where his father was minister. He discovered very early a good genius and a strong inclination for learning; which was carefully improved by a suitable education. He had also that prudence and sagacity, which led him to pursue literature by sure and proper steps, acquiring a kind of mastery in one science before he proceeded to another. His father had designed him for the ministry; but seeing his inclination did not lie that way, he prudently left him to pursue the bent of his genius. Accordingly young Nieuwentyt, apprehending that nothing was more useful than fixing his imagination and forming his judgment well, applied himself early to logic, and the art of reasoning justly, in which he grounded himself on the principles of Descartes, with whose philosophy he was greatly delighted. From thence he proceeded to the mathematics, in which he made a considerable proficiency; though the application he gave to that branch of learning did not prevent him from studying both law and physic. In fact he succeeded in all these sciences so well, as deservedly to acquire the character of a good philosopher, a great mathematician, an expert physician, and an able and just magistrate.

Though he was naturally of a grave and serious disposition, yet he was very affable and agreeable in conversation. His engaging manner procured the affection of every one; and by this means he often drew over to his opinion those who before differed very widely from him. Thus accomplished, he acquired a great esteem and credit in the council of the town of Puremerende, where he resided; as he did also in the states of that province, who respected him the more, inasmuch as he never engaged in any cabals or factions, in order to secure it; regarding in his conduct, an open, honest, upright behaviour, as the best source of satisfaction, and relying solely on his merit. In fact, he was more attentive to cultivate the sciences, than eager to obtain the honours of the government; contenting himself with being counsellor and burgomaster, without courting or accepting any other posts, which might interfere with his studies, and draw him too much out of his library.—Nieuwentyt died the 7th of March 1730, at 76 years of age, having been twice married.—He was author of several works, in the Latin, French, and Dutch languages, the principal of which are the following.

1. A Treatise in Dutch, proving the Existence of God by the Wonders of Nature; a much esteemed work, which went through many editions. It was translated also into several languages, as the French, and the English, under the title of, The Religious Philosopher, &c.

2. A Refutation of Spinoza, in the Dutch language.—3. Analysis Infinitorum; 1695, 4to.—4. Considerationes secundæ circa Calculi Differentialis Principia; 1696, 8vo.—In this work he attacked Leibnitz, and was answered by John Bernoulli and James Herman.—5. A Treatise on

the New Use of the Tables of Sines and Tangents.—6. A Letter to Bothnia or Burmania, on the Subject of Meteors.

NITROGEN, or NITROUS GAS, (the phlogisticated air of Priestley,) forms the unrespirable part of atmospheric air, and exists in it in the proportion of 78 per cent, estimated by bulk, or 74 per cent. by weight. See Aikin's Chemical Dictionary, article AZOTE.

NIGHT, that part of the natural day, during which the sun is below the horizon: though sometimes it is understood that the twilight is referred to the day, or the time the sun is above the horizon; the remainder only being the night. Under the equator, the nights, in the former sense, are always equal to the days; each being 12 hours long. But under the poles, the night continues half a year.—The ancient Gauls and Germans divided their time not by days, but nights; as appears from Cæsar and Tacitus; also the Arabs and the Icelanders do the same. The same may also be observed of our Saxon ancestors: whence our custom of saying, sevennight, fortnight, &c.

NOCTILUCA, a species of phosphorus, so called because it shines in the night, without any light being thrown on it: such is the phosphorus made of urine. By which it stands distinguished from some other species of phosphorus, which require to be exposed to the sun-beams before they will shine; as the Bononian-stone, &c. Mr. Boyle has a particular treatise on this subject.

NOCTURNAL *Arch*, is the arch of a circle described by the sun, or a star, in the night.

NOCTURNAL, or NOCTURLABIUM, denotes an instrument, chiefly used at sea, to take the altitude or depression of the pole-star, and some other stars about the pole, for finding the latitude, and the hour of the night.

There are several kinds of this instrument; some of which are projections of the sphere; such as the hemispheres, or planispheres, on the plane of the equinoctial. The seamen commonly use two kinds; the one adapted to the pole-star, and the first of the guards of the Little Bear; the other to the pole-star and the pointers of the Great Bear.

The nocturnal consists of two circular plates (fig. 15, pl. 17) applied over each other. The greater, which has a handle to hold the instrument, is about 2½ inches diameter, and is divided into 12 parts, answering to the 12 months; also each month subdivided into every 5th day; and in such manner, that the middle of the handle corresponds to that day of the year in which the star here respected has the same right ascension with the sun.

When the instrument is fitted for two stars, the handle is made moveable. The upper circle is divided into 24 equal parts, for the 24 hours of the day, and each hour subdivided into quarters, as in the figure. These 24 hours are denoted by 24 teeth; to be told in the night. In the centre of the two circular plates is adjusted a long index A, moveable on the upper plate. And the three pieces, viz, the two circles and index, are joined by a rivet which is pierced through the centre, with a hole 2 inches in diameter, for the star to be observed through.

To Use the NOCTURNAL. Turn the upper plate till the longest tooth, marked 12, be against the day of the month on the under plate; and bringing the instrument near the eye, suspend it by the handle, with the plane nearly parallel to the equinoctial; then viewing the pole-star through the hole in the centre, turn the index about till, by the edge coming from the centre, you see the bright star or guard of the Little Bear, if the instrument be fitted to that star: then that tooth of the upper circle, under the edge of the index, is at the hour of the night on the edge of the hour-circle, which may be known without a light, by counting the teeth from the longest, which is for the hour of 12.

NODATED *Hyperbola*, one, so called by Newton, which by turning round decussates or crosses itself: as in the 2d, and several other species, of his Enumeratio Linearum Tertii Ordinis.

NODES, the two opposite points where the orbit of a planet intersects the ecliptic. That, where the planet ascends from the south to the north side of the ecliptic, is called the ascending node, or the Dragon's head in the moon, and marked thus ☊: and the opposite point, where the planet descends from the north to the south side of the ecliptic, is called the descending node, or Dragon's tail in the moon, and is thus marked ☋. Also the right line drawn from the one node to the other, is called the line of the nodes.

By observation it appears that, in all the planets, the line of the nodes continually changes its place, its motion being in antecedentia; i. e. contrary to the order of the signs, or from east to west; with a peculiar degree of motion for each planet. Thus, by a retrograde motion, the line of the moon's nodes completes its circuit in 18 years and 225 days, in which time the node returns again to the same point of the ecliptic. Newton has not only shown, that this motion arises from the action of the sun, but, from its cause, he has with great skill calculated all the elements and varieties in this motion. See his Princip. lib. 3, prop. 30, 31, &c.—The moon must be in or near one of the nodes, to make an eclipse either of the sun or moon.

For a full treatise on the nodes of the planets, see Lalande's Astronomy, in many articles as shown by the index at the end of the 3d volume, and the result of the whole in vol. 2, pa. 124, where he gives a table of the nodes of the several planets, for the year 1750, and their annual variations, thus:

Planets' ascending Nodes in 1750.

Planets.	Node ☊ in 1750.				Annual decrease.
Mercury	1ˢ	15°	21′	15″	45′
Venus	2	14	26	18	31
Mars	1	17	36	30	39·8
Jupiter	3	8	16	0	60
Saturn	3	21	31	17	30
Herschel	2	11	49	30	

See also our article ORBIT.

NODUS, or *Node*, in Dialling, denotes a point or hole in the gnomon of a dial, by the shadow or light of which is shown, either the hour of the day in dials without furniture, or the parallels of the sun's declination, and his place in the ecliptic, &c, in dials with furniture.

NOLLET (*the Abbé* JOHN ANTHONY), a considerable French philosopher, and a member of most of the philosophical societies and academies of Europe, was born at Pimpré, in the district of Noyon, the 19th of November 1700. From the profound retreat, in which the mediocrity of his fortune obliged him to live, his reputation continually increased from day to day. M. Dufay associated him in his Electrical Researches; and M. de Reaumur resigned to him his laboratory. It was under these masters that he developed his talents. M. Dufay took him along with him in a journey he made into England; and Nollet profited so well of this opportunity, as to institute a friendly and literary correspondence with some of the most celebrated men in this country.

The king of Sardinia gave him an invitation to Turin, to perform a course of experimental philosophy to the duke of Savoy. From thence he travelled into Italy, where he collected some good observations concerning the natural history of the country.

In France he was master of philosophy and natural history to the royal family; and professor-royal of experimental philosophy to the college of Navarre, and to the schools of artillery and engineers. The Academy of Sciences appointed him adjunct-mechanician in 1739, associate in 1742, and pensioner in 1757. Nollet died the 24th of April 1770, regretted by all his friends, but especially by his relations, whom he always succoured with an affectionate attention. The works published by Nollet, are the following:

1. Recueils de Lettres sur l'Electricité; 1753, 3 vols in 12mo.—2. Essai sur l'Electricité des Corps; 1 vol. in 12mo.—3. Recherches sur les Causes particulieres des Phenomenes Electriques; 1 vol. in 12mo.—4. L'Art des Experiences; 1770, 3 vols in 12mo.

His papers printed in the different volumes of the Memoirs of the Academy of Sciences, are much too numerous to be particularized here; they are inserted in all or most of the volumes from the year 1740 to the year 1767 inclusive, and generally several papers in each volume.

NONAGESIMAL, or NONAGESIMAL *Degree*, called also the mid-heaven, is the highest point, or 90th degree of the ecliptic, reckoned from its intersection with the horizon at any time; and its altitude is equal to the angle that the ecliptic makes with the horizon at their intersection, or equal to the distance of the zenith from the pole of the ecliptic. It is much used in the calculation of solar eclipses.

NONAGON, a figure having nine sides and angles.—In a regular nonagon, or that whose angles, and sides, are all equal, if each side be 1, its area will be 6·1818242 = $\frac{9}{4}$ of the tangent of 70°, to the radius 1. See my Mensuration, pa. 85, 4th edit.

NONES, in the Roman Calendar, the 5th day of the months January, February, April, June, August, September, November, and December; and the 7th of the other months March, May, July, and October: these last four months having 6 days before the nones, and the others only four.—They had this name probably, because they were always 9 days inclusively, from the first of the nones to the ides, i. e. reckoning inclusively both those days.

NONIUS, or NUNEZ (PETER), an eminent Portuguese mathematician and physician, was born in 1497, at Alcazar in Portugal, anciently a remarkable city, known by the name of Salacia, whence he was surnamed Salaciensis. He was professor of mathematics in the university of Coimbra, where he published some pieces which procured him great reputation. He was mathematical preceptor to Don Henry, son to king Emanuel of Portugal, and principal cosmographer to the king. Nonius was very serviceable to the designs which this court entertained, of carrying on their maritime expeditions into the East, by the publication of his book On the Art of Navigation, and various other works. He died in 1577, at 80 years of age.

Nonius was the author of several ingenious works and inventions, and was justly esteemed one of the most eminent mathematicians of his age. Concerning his Art of Navigation, father Dechales says, "In the year 1530, Peter Nonius, a celebrated Portuguese mathematician, on occasion of some doubts proposed to him by Martinus Alphonsus Sofa, wrote a Treatise on Navigation, divided into two books; in the first, he answers some of those doubts, and explains the nature of loxodromic lines. In the second book, he treats of rules and instruments proper for navigation, particularly sea-charts, and instruments serving to find the elevation of the pole; but says he is rather obscure in his manner of writing."—Furetiere, in his Dictionary, takes notice that Peter Nonius was the first who, in 1530, invented the angles which the loxodromic curves make with each meridian, calling them in his language Rhumbs, and which he calculated by spherical triangles. Stevinus acknowledges, that Peter Nonius was scarce inferior to the very best mathematicians of the age. And Schottus says, he explained a great many problems, and particularly the mechanical problem of Aristotle on the motion of vessels by oars. His Notes upon Purbach's Theory of the Planets, are very much to be esteemed: he there explains several things, which had either not been noticed before, or not rightly understood.

In 1542, he published a Treatise on the Twilight, which he dedicated to John the 3d, king of Portugal; to which he added what Alhazen, an Arabian author, has composed on the same subject. In this work he describes the method or instrument called, from him, a Nonius; a particular account of which see in the following article.—He corrected several mathematical mistakes of Orontius Finæus.—But the most celebrated of all his works, or that at least he appeared most to value, was his Treatise of Algebra, which he had composed in Portuguese, but translated it into the Castilian tongue, when he resolved to make it public, which he thought would render his book more useful, as this language was more generally known than the Portuguese. The dedication, to his former pupil, prince Henry, was dated from Lisbon, Dec. 1, 1564. This work contains 341 leaves, or 682 pages, in the Antwerp edition of 1567, in 8vo; the folios being numbered only on one side.

The catalogue of his works, chiefly in Latin, is this:

1. De Arte Navigandi, libri duo; 1530.—2. De Crepusculis; 1542.—3. Annotationes in Aristotelem.—4. Problema Mechanicum de Motu Navigii ex Remis.—5. Annotationes in Planetarum Theorias Georgii Purbachii, &c.—6. Libro de Algebra en Arithmetica y Geometra; 1564.

All these pieces, the Algebra excepted, were collected and published, in a folio volume, at Basil, in 1566.

NONIUS, is a name also erroneously given to the method of graduation now generally used in the division of the scales of various instruments, and which should be called Vernier, from its real inventor. The method of Nonius, so called from its inventor Pedro Nunez, or Nonius, and described in his treatise De Crepusculis, printed at Lisbon in 1542, consists in describing within the same quadrant, 45 concentric circles, dividing the outermost into 90 equal parts, the next within into 89, the next into 88, and so on, till the innermost was divided into 46 only. By this means, in most observations, the plumb-line or index must cross one or other of those circles in or very near a point of division: whence, by calculation, the degrees and minutes of the arch might easily be obtained. This method is also described by Nunez, in his treatise De Arte et Ratione Navigandi, lib. 2. cap. 6, where he imagines it was not unknown to Ptolemy. But as the degrees are thus divided unequally, and it is very difficult to attain exactness in the division, especially when the numbers, into which the arches are to be divided, are incomposite, of which there are no less than nine, the method of diagonals first published by Thomas Digges, Esq. in his treatise Alæ seu Scalæ Mathematicæ, printed at Lond. in 1573, and said to be invented by one Richard Chanseler, a very skilful artist, was substituted in its stead. However, Nonius's method was improved at different times; but the commodious division now so much in use, is the most considerable improvement of it. See VERNIER; also Robertson's Navigat. Pref. p. iv; or Robins's Tracts, v. 2, p. 265, for a curious history of many other such contrivances.

NORMAL, is used sometimes for a perpendicular.

NORTH *Star*, called also the Pole-star, is the last in the tail of the Little Bear.

NORTHERN *Signs*, are those six that are on the north side of the equator; viz. Aries, Taurus, Gemini, Cancer, Leo, Virgo.

NORTHING, in Navigation, is the difference of latitude, which a ship makes in sailing northwards.

NORWOOD (RICHARD), a respectable teacher of mathematics, in London, especially navigation, in which it seems he had some practice. He published several useful books; as, 1. The Epitome and Doctrine of Triangles, 1673, in 8vo; 2. Trigonometry, 1685, in 4to; 3. The Seaman's Practice, 1697, in 4to; where we find that for which he has been chiefly noted, viz. his determination of the magnitude of the earth, and the degrees of the meridian, by means of the distance measured between London and York, in the year 1635. This measurement at so early a date, was ingeniously devised, and simply executed, reflecting on the author considerable credit, whose means and convenience for the performance were small and humble. The deviation from an accurate result is however not so considerable as might be expected from the rude manner of his measuring with a chain, along the high road in all directions, to the right and left, as well as up and down hills, and sometimes only by pacing or stepping the distances. It seems however he did not make a sufficient allowance for those zigzag directions and estimations, as his conclusion gives the mean length of a degree of latitude too great by almost half a mile, viz. $69\frac{5}{11}$ miles to a degree, instead of $69\frac{1}{11}$, as deduced from later and more accurate measurements.

Mr. N. had also an ingenious paper on the Tides, on Wells, on Salt and Fresh Water, and on Whale-fishing, inserted in the Philos. Trans. an. 1667, or in my Abridgement, vol. 1, pa. 206.

NOSTRADAMUS (MICHEL), an able physician and celebrated astrologer, was born at St. Remy in Provence, in the diocese of Avignon, December 14, 1503. His father was a notary-public, and his grandfather a physician, from whom he received some tincture of the mathematics. He afterwards completed his courses of languages and philosophy at Avignon. Hence, going to Montpelier, he applied himself to physic; but being forced away by the plague, he travelled through different places till he came to Bourdeaux, undertaking all such patients as were willing to put themselves under his care. This course occupied him five years; after which he returned to Montpelier, and was created doctor of his faculty in 1529; after which he revisited the same places where he had practised physic before. At Agen he formed an acquaintance with Julius Cæsar Scaliger; but quitted it after a residence of about 4 years. He next settled at Marseilles, but repaired to Salon about the year 1544.

In 1546, Aix being afflicted with the plague, he went thither at the solicitation of the inhabitants, to whom he rendered great service, particularly by a powder of his own invention: so that the town, in gratitude, gave him a considerable pension for several years after the contagion ceased. In 1547 the city of Lyons, being visited with the same distemper, had recourse to our physician, who attended them also. Afterwards returning to Salon, he began a more retired course of life, and in this time of leisure applied himself closely to his studies. He had for a long time followed the trade of a conjurer occasionally; and now he began to fancy himself inspired, and miraculously illuminated with a prospect into futurity. As fast as these illuminations had discovered to him any future event, he entered it in writing, in simple prose, though in enigmatical sentences: but revising them afterwards, he thought the sentences would appear more respectable, and savour more of a prophetic spirit, if they were expressed in verse. This opinion determined him to throw them all into quatrains, and he afterward ranged them into centuries. For some time he could not venture to publish a work of this nature; but afterwards perceiving that the time of many events foretold in his quatrains was very near at hand, he resolved to print them, as he did, with a dedication addressed to his son Cæsar, an infant only some months old, and dated March 1, 1555. To this first edition, which comprised but 7 centuries, he prefixed his name in Latin, but gave to his son Cæsar the name as it is pronounced in French, Notradame.

The public were divided in their sentiments of this work: many considered the author as a simple visionary; by others he was accused of magic or the black art, and treated as an impious person, who held a commerce with the devil; while great numbers believed him to be really endued with the supernatural gift of prophecy. However, Henry the 2d, and queen Catharine of Medicis, his mother, were resolved to see our prophet, who receiving orders to that effect, he presently repaired to Paris; where he was very graciously received at court, and received a present of 200 crowns. He was sent afterwards to Blois, to visit the king's children there, and report what he should be able to discover concerning their destinies. It is not known what his prediction was; however he returned to Salon loaded with honour, and good presents.

Animated with this success, he augmented his work to the number of 1000 quatrains, and published it with a dedication to the king in 1558. That prince dying the next year of a wound which he received at a tournament, our prophet's book was immediately consulted; and this unfortunate event was found in the 35th quatrain of the first century, which runs thus in the London edition of 1672:

Le Lion jeune le vieux surmontera,
En champ bellique, par singulier duelle,
Dans cage d'or l'œil il lui crevera,
Deux playes une, puis mourir mort cruelle.

In English thus, from the same edition:

The young Lion shall overcome the old one,
In martial field by a single duel,
In a golden cage he shall put out his eye,
Two wounds from one, then he shall die a cruel death.

So remarkable a prediction added new wings to his fame; and he was honoured soon after with a visit from Emanuel duke of Savoy, and the princess Margaret of France, his consort. From this time Nostradamus found himself even overburthened with visitors, and his fame made every day new acquisitions. Charles the 9th, coming to Salon, was eager above all things to have a sight of him: Nostradamus, who then was in waiting as one of the retinue of the magistrates, being instantly presented to the king, complained of the little esteem his countrymen had for him; upon which the monarch publicly declared that he should hold the enemies of Nostradamus to be his enemies, and desired to see his children. Nor did that prince's favour stop here; in passing, not long after, through the city of Arles, he sent for Nostradamus, and presented him with a purse of 200 crowns, together with a brevet, constituting him his physician in ordinary, with the same appointment as the rest. But our prophet enjoyed these honours only a short time, as he died 16 months after, viz, July 2, 1566, at Salon, being then in his grand climacteric, or 63d year.—He had published several other pieces, chiefly relating to medicine.

He left three sons and three daughters. Cæsar the eldest son was born at Salon in 1555, and died in 1629: he left a manuscript, giving an account of the most remarkable events in the history of Provence, from 1080 to 1494, in which he inserted the lives of the poets of that country. These memoirs falling into the hands of his nephew Cæsar Nostradamus, gentleman to the duke of Guise, he undertook to complete the work, and being encouraged by the estates of the country, he carried the account up to the Celtic Gauls: the impression was finished at Lyons in 1614, and published under the title of Chronique de l'Histoire de Provence.—The second son, John, exercised with reputation the business of a proctor in the parliament of Provence.—He wrote the Lives of the Ancient Provençal Poets, called Troubadours, and the work was printed at Lyons in 1575, 8vo.—The youngest son it is said undertook the trade of peeping into futurity like his father.

NOTATION, is the representing of any given number by means of certain significant characters, or numerical symbols; and thus stands in contradistinction to Numeration, which is the wording or expressing in words any number represented by those symbols.

It is highly probable, that in the early stages of society, every distinct number had a peculiar characteristic representative, which must however have led to great difficulty and embarrassment, on account of the number of different characters with which the memory must have been incumbered; at the same time it must also have been very limited in its application. Therefore, as soon as the state of society required the use of great numbers, which must have immediately followed the introduction of commerce, it became necessary to have a more concise notation; and the most proper method of accomplishing this, was that of giving to each symbol a local as well as a simple value. This however was a refinement that could hardly be expected in the first rude efforts of the human mind; and probably there are now no traces left of the first attempt of this kind.

We know now of only three different modes of notation, namely; the Roman, the Grecian, and the Indian; the latter of which is the only one at present in use, at least in arithmetical calculations: but each of these agree in one material point, which is that of dividing all numbers into periods of tens, a custom almost universally adopted by all nations; and as this is not the best number that might have been employed for forming the radix of a system of arithmetic, we must look to some general physical cause, for this singular coincidence of different people, many of whom had probably no communication with each other.

Mathematicians, so far back as the time of Aristotle, have noticed this singularity; and have endeavoured to account for it from different principles: it had, however, no doubt, its origin in the natural formation of man. Every one in the infancy of his reason makes the first efforts of calculation on his fingers, which being ten in number, evidently led to the separation of quantities of all kinds into periods of tens. For after having counted to this number, they were under the necessity of beginning again, and committing to their memory that they had already counted one period of ten: having then completed a second, third, &c, period, they still continued to count in the same manner, and still employed their fingers, as the proper instruments for assisting the memory in retaining the number of those periods, as well as for still pursuing their calculations: this therefore necessarily led to the second principal separation of number into hundreds; and so on for thousands, tens of thousands, &c.

Hence it appears, that the idea of our present scale of notation had, in reality, its foundation in the structure of the human frame: but to what nation we are indebted for the method of expressing numbers by means of ten simple characters, by giving to each a local, as well as a primitive value, is unknown: it is however pretty evident that it is only an improvement on the first rude attempts at numbering, above-mentioned.

The honour of this invention has been ascribed to different nations; some have attributed it to the Greeks, others to the Arabs, the Chaldeans, Indians, &c.

The first traces of it however, that have been discovered, are among the Arabs, who themselves attribute it to the Indians; but whether it had its origin with those people, or they derived it from any other nation, is a very doubtful question, which will perhaps ever remain undecided.

Montucla, in his Histoire des Mathematiques, book 2, vol. 1, has entered minutely into the subject, and has shown in the most unequivocal manner, not only that the Indians were in possession of this art before it was known to the Arabs, but also that the characters employed by them 2000 years back, did not very materially differ from those in present use; and it is to this work we are indebted for the specimen of the ancient and modern characters that we have given in plate 23, the last line of which is Al-Sephadi's expression for the number 18446744073709551615; and each of the other lines stands opposite the name of the author, or the nation, by whom they have been employed. From these specimens it will be readily perceived how our modern symbols have been derived, with some slight modifications, from those of the most ancient date.

It has been before observed, that almost all nations have adopted, as it were by common consent, the decimal scale of notation: this is not however without some exceptions. The ancient Chinese are said to have employed the binary scale (see BINARY), and a nation of Thrace, mentioned by Aristotle, used the quaternary scale, counting by periods of fours; and another people bordering on Senegal, make all their calculations by periods of fives, which they designate as follows; one, two, three, four, five, they call *ben, niard, niet, guyanet, guiron;* and six, seven, eight, nine, by *guiron ben, guiron niard, guiron niet,* &c. and ten by *fouque,* and probably eleven by *fouque ben.*

But these exceptions to the general mode of notation are very inconsiderable, and none of those scales that we have mentioned are by any means so well adapted to arithmetical purposes as our own; but this it must be acknowledged is inferior in many respects to the duodenary scale; which, by the addition of two extra characters, would perform all arithmetical operations with greater ease and expedition; and with respect to decimals, or duodecimals, as they would be in that case, we should have a great many more finite expressions than we have at present. In the decimal scale, if we consider only the reciprocals of all numbers under 20, we find only the six following that give finite decimals:

$\frac{1}{2} = \cdot 5$; $\frac{1}{4} = \cdot 25$; $\frac{1}{5} = \cdot 2$; $\frac{1}{8} = \cdot 125$; $\frac{1}{10} = \cdot 1$; $\frac{1}{16} = \cdot 0625$; but in the duodenary scale, we have nine finite expressions with the same numbers, which are as follows;

$\frac{1}{2} = \cdot 6$; $\frac{1}{3} = \cdot 4$; $\frac{1}{4} = \cdot 3$; $\frac{1}{6} = \cdot 2$; $\frac{1}{8} = \cdot 16$;
$\frac{1}{9} = \cdot 14$; $\frac{1}{12} = \cdot 1$; $\frac{1}{16} = \cdot 09$; $\frac{1}{18} = \cdot 08$.

Hence it is evident that, with this scale of notation, we should have more finite fractional numbers than in our common arithmetic; and beside this convenience, all operations would be more readily performed, and larger numbers would be expressed with fewer digits. Still however the advantages of this system are not such as can lead us to expect, or even to wish, that it should ever be substituted for that, which long established practice has rendered so familiar to all our ideas of numbers.

NOTATION *of the Greeks.* The Grecian notation, though it approached in many respects very near to that of the moderns, still it wanted one principal and distinguishing feature of the present improved system, which is that of giving to every character, a local as well as a simple value, for want of which they were under the necessity of employing a great number of characters, which were chiefly derived from the letters of their alphabet.

Instead of the figures	1,	2,	3,	4,	5,	6,	7,	8,	9,
The Greeks made use of these letters	α,	β,	γ,	δ,	ε,	ϛ,	ζ,	η,	θ.
And instead of	10,	20,	30,	40,	50,	60,	70,	80,	90,
They employed the characters	ι,	κ,	λ,	μ,	ν,	ξ,	ο,	π,	ϟ.
For expressing the hundreds they had	ρ,	σ,	τ,	υ,	φ,	χ,	ψ,	ω,	ϡ,
And for the thousands they employed	͵α,	͵β,	͵γ,	͵δ,	͵ε,	͵ϛ,	͵ζ,	͵η,	͵θ.

That is, they had recourse to the characters of the simple units, but instead of giving to them a local value, as we do, and in which consists the superiority of the modern method, they distinguished them by means of a small dash placed at the bottom of the letters. And hence we see that the Greeks could express with these characters any number under 10,000; thus,

9999 they represented		by	͵θϡϟθ
7382	- -	by	͵ζτπβ
8036	- -	by	͵ηλϛ
6420	- -	by	͵ϛυκ
4001	- -	by	͵δα
3000	- -	by	͵γ

10000 was sometimes expressed by placing a small dash over the iota; thus, ῑ; but mathematicians, in their calculations, generally employed for this purpose the compound character $\overset{\alpha}{\mathrm{M}}$; and any number of times this period, by placing the letter M under the characters expressing the number of periods that they wished to indicate; thus,

10000 was represented		by	$\overset{\alpha}{\mathrm{M}}$
20000	- -	by	$\overset{\beta}{\mathrm{M}}$
30000	- -	by	$\overset{\gamma}{\mathrm{M}}$
100000	- -	by	$\overset{\iota}{\mathrm{M}}$
800000	- -	by	$\overset{\pi}{\mathrm{M}}$
972000	- -	by	$\overset{ϡοβ}{\mathrm{M}}$

So that placing the letter M under any given number had the same effect as our annexing four ciphers.

Diophantus and Pappus deviated a little in this respect from their predecessors, by making Mυ the characteristic of 10000, and then distinguishing any number of those periods by prefixing the number to this character; thus, the foregoing numbers, according to these authors, were represented by αMυ, βMυ, γMυ, ιMυ, πMυ, ϡοβMυ, &c.

And where smaller numbers were mixed with those larger periods, they were annexed to the foregoing characters; hence,

1719999 was written ροαMυ͵θϡϟθ

43728097 - δτοβMυ͵ηϟζ

Thus resembling what we make use of at this day for expressing compound numbers, as 7ft 6in 7pts.

The same authors also sometimes employed a still more simple method, which was by omitting the character Mυ, and only separating the two sets of symbols by a point.

Thus 99999999 was written ͵θϡϟθ.͵θϡϟθ, which was the largest number that the Greeks could express; and therefore, when they wanted to make use of larger numbers than this, they were under the necessity of assuming a larger unit; several examples of which are to be met with in the ancient Greek authors.

Apollonius at length conceived the idea of dividing all numbers into periods of four characters, the first of which represented units, the second the number of 10000, the third the square of 10000's, &c. This was a great step towards our present system, for here was evidently a local value given to the different periods, and the same only wanted to have been carried downwards to the units, to have completed the discovery.

In this manner the circumference of a circle whose diameter is 1, according to the notation of Apollonius, would be expressed by

γ . ͵αυιε . ͵θσξε . ͵γφπθ . ͵ζϡλβ . ͵γωμϛ . ͵βχμγ.

3 . 1415 . 9265 . 3589 . 7932 . 3846 . 2643.

From what has been already observed, it appears, that the Greek notation resembled what we now employ for compound numbers, and in short their whole arithmetic differed from ours chiefly in this, that for want of giving a local value to their characters, all their operations were performed much in the same manner as we now perform ours in duodecimals, and compound multiplication, division, &c. None of the Greek writers whose works have come down to us, have attempted to teach the first fundamental rules of their arithmetic; we can therefore only judge from the disposition of their characters, the exact method of operation that they followed. It seems however probable, that they generally worked from the left hand towards the right; but in their additions and subtractions this was so manifestly disadvantageous and troublesome, compared with what it would have been to have performed the same operations in a contrary order, that one can hardly suppose they could have overlooked such an evident and advantageous proceeding.

As to their multiplications, it was not of so much importance, and there seems no doubt that in this rule, their operations were performed from left to right, as we do ours in algebra. In their divisions they approached nearer to our method for compound division, except that they generally found the whole quotient at one step, which must therefore have been the result of several tedious trials, or by means of a table for that purpose; that is, they found the greatest quotient in the first period, and then, having subtracted, they found the second period of the quotient, &c. The square root was extracted in a manner also much resembling ours, differing from it, only in finding each period of the root at one step, as they did the quotients in division.

It would be inconsistent with the nature of our work to enter upon this subject at any considerable length, we shall therefore confine ourselves to exhibiting a few examples, with the corresponding operations in our arithmetic, referring the curious reader for farther information on this head, to an ingenious and learned Essay, by Delambre, added to the French translation of the works of Archimedes, where he will find ample gratification.

Example in Addition.

Greek	ωμζ . ͵γϡκα	Modern	847 3921
	ξ . ͵ηυ		60 8400
	ϡη . ͵βτκα		908 2321

Example in Subtraction.

Greek	θ . ͵γχλϛ	Modern	9 3636
	β . ͵γυθ		2 3409
	ζ . σκζ		7 0227

Example in Multiplication.

ρνγ	153
ρνγ	153
͵α.ͺετ	15300 = 100 . 153
͵ε͵βρϟν	7650 = 50 . 153
τϟνθ	459 = 3 . 153
β.͵γυθ	23409

The above examples will convey a slight idea of the notation of the Greeks, and their method of performing the fundamental rules of their arithmetic, which is evidently, in every respect, very much inferior to that of the moderns.

Roman NOTATION. The Romans also employed some of the letters of their alphabet for designating different numbers, which, though sufficiently commodious in point of representation, was by no means adapted for arithmetical calculations. The simple characters were as follow:

1	was represented	by I
5	- -	by V
10	- -	by X
50	- -	by L
100	- -	by C
500	- -	by D
1000	- -	by M

And by means of these characters, and the various combination of them, they expressed any number whatever. These are still in use for representing dates, numbering of chapters, pages, &c.

NOTES, in Music, are characters which mark the tones, i. e. the elevations and fallings of the voice, or sound, and the swiftness or slowness of its motions, &c; and these have undergone various alterations and improvements, before they arrived at their present state of perfection.

NOVEMBER, the eleventh month in the Julian year, but the ninth in the year of Romulus, beginning with March; whence its name. In this month, which contains 30 days, the sun enters the sign ♐, viz, usually about the 21st day of the month.

NUCLEUS, the kernel, is used by Hevelius, and some other astronomers, for the body of a comet, which others call its head, as distinguished from its tail, or beard.

NUCLEUS, is also used by some writers for the central parts of the earth, and other planets, which they suppose firmer, and as it were separated from them, considered as a cortex or shell.

NUEL, the same as NEWEL of a Staircase.

NUMBER, a collection or assemblage of several units, or several things of the same kind; as 2, 3, 4, &c, exclusive of the number 1: which is Euclid's definition of number.—Stevinus defines number as that by which the quantity of any thing is expressed: agreeably to which Newton conceives a number to consist, not in a multitude of units, as Euclid defines it, but in the abstract ratio of a quantity of any kind to another quantity of the same kind, which is accounted as unity: and in this sense, including all these three species of number, viz, Integers, Fractions, and Surds.

Wolfius defines number to be something which refers to unity, as one right line refers to another. Thus, assuming a right line for unity, a number may likewise be expressed by a right line. And in this way also Descartes considers numbers as expressed by lines, where he treats of the arithmetical operations as performed by lines, in the beginning of his Geometry.

Mathematicians divide number into different classes; as,

NUMBERS, *Absolute, Abstract, Abundant, Amicable, Applicate, Circular, Concrete, Composite, Cubic, Defective, Fractional, Figurate, Polygonal, Perfect, Prime, Pyramidal, Rational, Similar, Square,* &c, for which see the respective adjectives.

Beside these divisions, which form the principal heads under which numbers are considered, they are also divided into *even* and *odd*, and formerly they were distinguished into *evenly even, evenly odd,* &c: but these denominations are now disused, and the same is expressed by saying, numbers of the form $4n$, $4n + 1$, $4n - 1$, &c; by which is to be understood that, in the first place, the number is exactly divisible by 4; in the second, the number being divided by 4 it leaves a remainder 1; and in the third place, when divided by 4, it leaves a remainder 3 or -1; and the same is implied when numbers are said to be of any other form as $7n + 1$, $7n + 3$, $11n + 2$, &c: this is a much more simple and general method of classing numbers, and is that which is now commonly employed.

We find from the different fragments that have been transmitted to us, some of which are found in the Elements of Euclid, that the ancient mathematicians had made some considerable progress in the investigation of the properties of numbers; but they wanted two powerful instruments, in order to fathom this subject, of which the moderns have availed themselves; these are the present mode of notation, which expresses numbers with so much facility, and the science of algebra, which generalizes the results, and with which we can operate with the same ease on known and unknown quantities. These inventions could not but have a powerful influence in promoting the progress of the science of numbers; and accordingly, we find the work of Diophantus, the most ancient author on algebra that we know of, is entirely dedicated to the properties of numbers, and contains many difficult questions which required considerable address and sagacity to resolve.

From Diophantus, to the time of Vieta and Bachet, mathematicians continued to occupy themselves with the subject of numbers, but without much success; at length Vieta, by adding a new degree of excellence to algebra, resolved many difficult problems relating to numbers. Bachet, in his work entitled Problêmes Plaisans et Délectables, gave a solution to all indeterminate equations of the first degree, by a method as ingenious, as it was general in its application. To the same ingenious author we are indebted for an excellent commentary on Diophantus, which was afterwards enriched by the marginal notes of Fermat, who was one of those that most contributed to bring this science to perfection, by the great variety of elegant theorems that he proposed, though he left many of them without demonstrations; they, however, had the effect of calling into action the talents of many eminent mathematicians. It was the custom at that time to propose questions by way of challenge to each other, the solutions to which were accordingly concealed, in order to secure to themselves, or to their nation, the honour of solving them; this was at least the case with the English and French mathematicians, between whom there was much rivalry at that time.

We are however inclined to think, that many of the theorems of Fermat were only the result of observation and trials, and that he himself never arrived at their demonstrations; though he expressly says, in one of his notes on Diophantus, pa. 180, that he was engaged in writing a work on this subject, which would contain multa varia et abstrusissima numerorum mysteria: and it has long been regretted by mathematicians that this work never appeared. Some celebrated foreign authors seem to attribute the circumstance to the ignorance of the persons into whose hands Fermat's papers were consigned at his death; but we are rather inclined to ascribe it to a different cause; we suppose that at the time the note was written, Fermat was really engaged in such a work, and expected to be able to complete the undertaking; but probably failing in some of his most celebrated theorems, he suppressed the work entirely: and this idea receives considerable strength from the circumstance of Euler having shown, that one at least of his theorems, though true in a great many cases, is not generally so. Fermat had said, that $2^x + 1$ is always a prime, if x be taken any number in the series 2, 4, 8, 16, &c; but Euler found that $2^{32} + 1 = 641 \times 6700417$, and therefore is not a prime number. It should however be observed, that Fermat had made no mention of his having demonstrated this theorem.

But of all those mathematicians who have treated on the science of numbers, Euler claims the most distinguished situation: we are also much indebted to the labours and ingenuity of Lagrange, Legendre, and Gauss. The two latter have published works expressly on this subject, entirely independent of each other's method, both of which possess a very great degree of merit; but the latter has the greatest claim to originality. The former work is in French, entitled Essai sur la Theorie des Nombres, par Legendre; the first edition of which was published in 4to, at Paris, in the year , and a second edition, with considerable improvements, in 1808. The latter work is in Latin, under the title of Disquisitiones Arithmeticæ, and it has since been translated into French.

It is impossible for us, in the space to which we must confined this article, to enter at length on the subject of numbers; we shall therefore confine ourselves to the enumeration of some of the most curious and important properties.

Properties of Numbers.

1. Every even number is of the form $2n$, and every odd number of the form $2n \pm 1$.

2. Every prime number, greater than 3, is contained in one of the formulæ $6n + 1$, or $6n - 1$; and every prime number greater than 2, in one of the forms $4n + 1$, or $4n - 1$.

3. Every even square number is of the form $4n$, and every odd square number of the form $8n + 1$.

4. The following table exhibits the forms of all square numbers, with regard to every modulus from 1 to 12.

Moduli.	Formulæ.			
2	$2n$	$2n + 1$		
3	$3n$	$3n + 1$		
4	$4n$	$4n + 1$		
5	$5n$	$5n \pm 1$		
6	$6n$	$6n + 1$	$6n + 4$	
7	$7n$	$7n + 1$	$7n + 2$	
8	$8n$	$8n + 1$	$8n + 4$	
9	$9n$	$9n + 1$	$9n + 4$	$9n + 7$
10	$10n$	$10n \pm 1$	$10n \pm 4$	$10n + 5$
11	$11n$	$11n + 1$	$11n + 4$	$11n + 9$
	$11n + 3$			
12	$12n$	$12n + 1$	$12n \pm 3$	$12n + 4$

And consequently every number that does not fall under some one of the above forms is not a square.

5. The following tables exhibit all the impossible forms of square numbers, as referred to the moduli 3, 4, and 5; that is, no number that falls under any of the forms in the table can be a square number.

Modulus 3.	Modulus 4.	Modulus 5.
$2t^2 \pm 3qu^2$	$2t^2 \backsim 4qu^2$	$2t^2 \backsim 5qu^2$
$3t^2 \pm 3qu^2$	$3t^2 \pm 4qu^2$	$3t^2 \backsim 5qu^2$
$5t^2 \pm 3qu^2$	$6t^2 \backsim 4qu^2$	$7t^2 \backsim 5qu^2$
$8t^2 \pm 3qu^2$	$10t^2 \pm 4qu^2$	$8t^2 \backsim 5qu^2$
$11t^2 \pm 3qu^2$	$11t^2 \backsim 4qu^2$	$12t^2 \backsim 5qu^2$
$14t^2 \pm 3qu^2$	$14t^2 \pm 4qu^2$	$13t^2 \backsim 5qu^2$
General Forms.	General Forms.	General Form.
$(3p+2)t^2 \pm 3qu^2$ and $3pt^2 + 3qu^2$	$(4p \pm 2)t^2 \backsim 4qu^2$ and $(4p+3)t^2 \pm 4qu^2$	$(5p \pm 2)t^2 \backsim 5qu^2$

Where it is only necessary to observe, that q and its respective moduli must be prime to each other.

6. The powers of all numbers from the 2d to the 12th (the 7th excepted), are of the following specified forms.

a^2	is one of the forms	$3n$	or	$3n + 1$
a^3	- -	$7n$	or	$7n \pm 1$
a^4	- -	$5n$	or	$5n + 1$
a^5	- -	$11n$	or	$11n \pm 1$
a^6	- -	$7n$	or	$7n + 1$
a^8	- -	$17n$	or	$17n \pm 1$
a^9	- -	$19n$	or	$19n \pm 1$
a^{10}	- -	$11n$	or	$11n + 1$
a^{11}	- -	$23n$	or	$23n \pm 1$
a^{12}	- -	$13n$	or	$13n + 1$

The 7th power is not reducible to a similar form, because neither $7 + 1$ nor $2 \times 7 + 1$ is a prime number.

7. Every prime number $8n + 1$, $8n + 5$, is, exclusively of all others, of the form $x^2 + y^2$; or, which is the same thing, every prime number of the form $4n + 1$ is the sum of two squares.

8. Every prime number $8n + 1$, $8n + 3$, is, exclusively of all others, of the form $x^2 + 2y^2$.

9. Every prime number $8n + 1$, $8n + 7$, is, exclusively of all others, of the form $x^2 - 2y^2$.

10. Every prime number $8n - 1$ is of the form $p^2 + q^2 + 2r^2$.

11. Every number of the form $24n + 5$ is the sum of five, or a less number of squares, whose roots are of the form $6n - 1$.

12. Every number of the form $8n + 6$, is the sum of six, or a less number of squares, whose roots are of the form $4m - 1$.

13. Every odd number, except those of the form $8n + 7$, is the sum of three squares. And no numbers of this form can be the sum of three squares.

14. Every odd number, without exception, is of the form $p^2 + q^2 + 2r^2$. It should be observed that in this form, as also in all others we have mentioned, any one or more of those squares may become zero.

15. Every number of the form $p^2 + q^2 + r^2$, when multiplied by 2, gives a number of the form $p^2 + q^2 + 2r^2$; and the latter form being multiplied again by 2, reproduces the former.

16. If a number be the sum of two squares, its double is the sum of two squares.

17. A number that is the sum of two squares, being multiplied by a number of the same form, gives a product that is the sum of two squares: that is, $(p^2 + q^2) \times (r^2 + s^2) = (x^2 + y^2)$.

18. The product of the sum of four squares, by the sum of four squares, is itself the sum of four squares; or,

$$(p^2 + q^2 + r^2 + s^2) \times (p'^2 + q'^2 + r'^2 + s'^2) = (w^2 + x^2 + y^2 + z^2).$$

19. Every number is a triangular number, or the sum of two or three triangular numbers. A square, or the sum of two, three, or four squares. A pentagonal, or the sum of two, three, four, or five pentagonals, &c.—This is one of the celebrated theorems of Fermat; but it has never been demonstrated, except for the two first cases. The other part of it still remains, to exercise the ingenuity of mathematicians.

20. Every number is a cube, or the sum of 2, 3, 4, 5, 6, 7, 8, or 9 cubes.—This is one of Dr. Waring's theorems, but we believe it has never been demonstrated.

21. If p and q be any two numbers prime to each other, then $p^2 + q^2$ can only be divided by numbers of the same form. Or, which is the same thing, a number that is the sum of two squares, can only be divided by numbers that are the sum of two squares: the two given squares being prime to each other.

22. And, in general, all numbers comprised in any of the following forms; viz, $p^2 + q^2$, $p^2 + 2q^2$, $p^2 - 2q^2$, can have for divisors, only those numbers which fall under the same form as themselves.

23. Every prime number $4n + 1$, which divides the formula $p^2 + 2q^2$, will also divide the formula $p^2 - 2q^2$.

24. A prime number $4n - 1$, that divides the formula $p^2 + aq^2$, can not be a divisor of the formula $p^2 - aq^2$.

25. Every prime number $8n + 1$, or $8n + 7$, will divide, at the same time, the two formulæ $p^2 + aq^2$, and $p^2 + 2aq^2$, or it will divide neither of them.

26. Every prime number $8n + 3$, or $8n + 5$, will always divide one of the two formulæ $p^2 + aq^2$, or $p^2 + 2aq^2$, but it can divide only one of them.

27. If c be a prime number, and n any number not divisible by c, then n divided by c, will leave the same remainder as n^c divided by c. Hence is readily deduced the following theorem, which is of the greatest use in the theory of numbers.

28. If c be a prime number, and n any number not divisible by c, then will $n^{c-1} - 1$ always be divisible by c.

29. If n be a prime number, then will $(1 \,.\, 2 \,.\, 3 \,.\, 4$ &c. $(n - 1) + 1)$ always be divisible by n.

This theorem is given in a more general form by M. Gauss, in his Disquisitiones Arithmeticæ; thus:

30. If n be any number whatever, and a, b, c, &c, all those numbers less than n, and also prime to it, then will $(a \,.\, b \,.\, c \,.$ &c. $(n - 1) + 1)$ be divisible by n.

From the former of these two enumerations is readily deduced the following corollary; namely,

31. If n be a prime number, then will $(1^2 \,.\, 2^2 \,.\, 3^2 \,.\, 4^2 \,.$ &c. $(\frac{n-1}{2})^2 + 1)$ when divided by n, always have a remainder ± 1; that is $+ 1$, when n is of the form $4n - 1$, and $- 1$ when n is of the form $4n + 1$.

32. If sa be made to represent the sum of all the divisors of any number a, then will $sn = s\,(n - 1) +$

$s(n-2) - s(n-3) - s(n-4) + s(n-5) + s(n-6) -$ &c.

33. Neither the sum nor difference of two cubes can be a cube.

34. Neither the sum nor difference of two biquadratures, can be a square.

35. And, generally, the equation $x^n \pm y^n = z^n$ is always impossible when n exceeds 2.—This is one of Fermat's theorems, which has never been demonstrated, except for the first two cases. Euler has generalized those cases, by demonstrating that the equation $a^2bx^4 \pm b^2ay^4 = z^2$ is always impossible.

36. The sum of any number of consecutive cubes, beginning at unity (or at any other number that is both a square and a cube), is a square number.

37. The second differences of consecutive square numbers is 2; the third difference of cubes is 6: and generally, the nth differences of the nth powers of any numbers in arithmetical progression, is constant, and is equal to $1 \times 2 \times 3 \times 4 \cdots (n-1) \times nd^n$, when d is the common difference of the series.

38. The area of a rational right-angled triangle cannot be a square number.

39. In any rational right-angled triangle, one of the sides is divisible by 5.

40. There cannot be more than three square numbers in an arithmetical progression.

41. The difference between any number, and another number formed with the same digits any how transposed, is always divisible by 9.

42. The difference between any odd power and its root, is divisible by double the exponent of that power.

43. The formula $a^m - a^n$ is always divisible by $a - 1$.

44. If $m - n$ be even, then will $a^m - a^n$ be divisible by $a + 1$.

45. If $m - n$ be odd, then will $a^m + a^n$ be divisible by $a + 1$.

46. The formula $a^m - b^m$ is always divisible by $a - b$, whatever be the value of m.

47. If m be even, then will $a^m - b^m$ be divisible both by $a - b$ and $a + b$.

48. If m be odd, then will $a^m + b^m$ be divisible by $a + b$.

49. No algebraical formula can be found that will contain prime numbers only.—This theorem is demonstrated by Legendre in his Essai sur la Theorie des Nombres.

50. The greatest known prime number is 2147483647.

The above numerical properties have been chiefly selected from Waring's Meditationes Algebraicæ; Euler's Anal. Infin., and his Algebra; Legendre's Essai sur la Theorie des Nombres; and from Gauss's Disquisitiones Arithmeticæ: to which works the reader is referred for every information that can be desired on this interesting subject.

Number, *Golden*. See Golden *Number* and Cycle.

Number *of Direction*, in Chronology, some one of the 35 numbers between the Easter limits, or between the earliest and latest day on which it can fall, i. e. between March 22 and April 25, which are 35 days; being so called, because it serves as a direction for finding Easter for any year; being indeed the number that expresses how many days after March 21, Easter-day falls. Thus, Easter-day falling as in the first line below, the number of direction will be as on the lower line:

	March										April		
Easter-day,	22,	23,	24,	25,	26,	27,	28,	29,	30,	31,	1,	2,	&c.
No. of dir.	1,	2,	3,	4,	5,	6,	7,	8,	9,	10,	11,	12,	&c

and so on, till the number of direction on the lower line be 35, which will answer to April 25, being the latest that Easter can happen. Therefore add 21 to the number of direction, and the sum will be so many days in March for the Easter-day: if the sum exceed 31, the excess will be the day of April.

To find the Number *of Direction*. Enter the following table (which is adapted to the new style), with the dominical letter on the left hand, and the golden number at the top, then where the columns meet is the number of direction for that year. See Ferguson's Astron. pa. 381, ed. 8vo.

G. N.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
Dom. Let.																			
A	29	19	5	26	12	33	19	12	26	19	5	26	12	5	26	12	33	19	12
B	27	13	6	27	13	14	20	13	27	20	6	27	13	6	10	13	34	20	6
C	8	14	7	21	14	35	21	7	28	21	7	28	14	7	21	14	28	21	7
D	19	15	8	22	15	29	22	8	29	15	8	29	15	1	22	15	29	22	8
E	30	16	2	23	16	20	28	9	30	16	9	28	16	9	23	9	30	23	9
F	24	17	3	24	10	31	24	10	31	17	10	24	17	3	24	10	31	17	10
G	25	18	4	25	11	32	18	11	12	18	4	25	18	4	25	11	32	18	11

Thus, for the year 1814, the dominical letter being B, and the golden number 10; on the line of B, and below 10, is 20 for the number of direction. To this add 21, the sum is 41 days from the 1st of March, which, deducting the 31 days of March, leaves 10 for the day of April, for Easter-day that year.

Numeral *Characters*. See Characters.

Numeral *Figures*. The antiquity of these in England has, for several reasons, been supposed as high as the eleventh century; in France about the middle of the tenth century; having been introduced into both countries from Spain, where they had been brought by the Moors or Saracens. See Wallis's Algebra, pa. 9 &c, and pa. 153 of additions at the end of the same; also Philos. Trans. No. 439 and 475. See also Notation.

NUMERATION, in Arithmetic, the art of estimating or pronouncing any number, or series of numbers.

Numbers are usually expressed by the ten following characters, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0; the first nine denoting respectively the first nine ordinal numbers; and the last, or cipher 0, joined to any of the others, denotes so many tens. In like manner, two ciphers joined to any one of the first nine significant figures, make it become so many hundreds, three ciphers make it thousands, and so on.

Weigelius indeed shows how to number, without going beyond a quaternary; i. e. by beginning to repeat at each fourth. And Leibnitz and De Lagny, in what they call their binary arithmetic, begin to repeat at every 2d place; using only the two figures 1 and 0. But these are rather matters of curiosity than use. See Notation.

That the nine significant figures may express not only units, but also tens, hundreds, thousands, &c, they have a local value given them, as hinted above; so that, though when alone, or in a right-hand place, they denote only units or ones, yet in the 2d place they denote tens, in the 3d place hundreds, in the 4th place thousands, &c; as the number 5555 is five thousand five hundred fifty and five.

Hence then, to express any written number, or assign the proper value to each character; beginning at the right hand, divide the proposed number into classes, of three characters to each class; and consider two classes as making up a period of six figures or places. Then every period, of six figures, has a name common to all the figures in it; the 1st being primes or units; the 2d is millions; the 3d is millions-of-millions, or billions; the 4th is millions-of-millions-of-millions or trillions; and so on; also every class, or half-period, of three figures, is read separately by itself, so many hundreds, tens, and units; only, after the left-hand half of each period, the word thousands is added; and at the end of the 2d, 3d, 4th &c period, its common name millions, billions, &c, is expressed. Thus, the number 4,591, is 4 thousand 5 hundred and 91.—The number 210,463, is 2 hundred and 10 thousands, and 463.—The number 281,427,307, is 281 millions, 427 thousands, and 307.

NUMERATOR, of a Fraction, is the number which shows how many of those parts, which the integer is supposed to be divided into, are denoted by the fraction. And, in the notation the numerator is set over the denominator, or number that shows into how many parts the integer is divided, in the fraction. So, ex. gr. $\frac{3}{4}$ denotes three-fourths, or 3 parts out of 4; where 3 is the numerator, and 4 the denominator.

NUMERICAL, Numerous, or *Numeral*, something that relates to number.

Numeral *Algebra*, is that which makes use of numbers, in contradistinction from literal algebra, or that in which the letters of the alphabet are used.

NUNEZ (Peter). See NONIUS.

NUTATION, in Astronomy, a kind of libratory motion of the earth's axis; by which its inclination to the plane of the ecliptic is continually varying, by a certain number of seconds, backwards and forwards. The whole extent of this change in the inclination of the earth's axis, or, which is the same thing, in the apparent declination of the stars, is about 19″, and the period of that change is little more than 9 years, or the space of time from its setting out from any point and returning to the same point again, about 18 years and 7 months, being the same as the period of the moon's motions, upon which it chiefly depends; being indeed the joint effect of the inequalities of the action of the sun and moon upon the spheroidal figure of the earth, by which its axis is made to revolve with a conical motion, so that the extremity of it describes a small circle, or rather an ellipse, of 19·1 seconds diameter, and 14″·2 conjugate, each revolution being made in the space of 18 years 7 months, according to the revolution of the moon's nodes.

This is a natural consequence of the Newtonian system of universal attraction; the first principle of which is, that all bodies mutually attract each other in the direct ratio of their masses, and in the inverse ratio of the squares of their distances. From this mutual attraction, combined with motion in a right line, Newton deduces the figure of the orbits of the planets, and particularly that of the earth. If this orbit were a circle, and if the earth's form were that of a perfect sphere, the attraction of the sun would have no other effect than to keep the earth in its orbit, without causing any irregularity in the position of its axis. But neither is the earth's orbit a circle, nor its body a sphere; for the earth is sensibly protuberant towards the equator, and its orbit is an ellipsis, which has the sun in its focus. Now when the position of the earth is such, that the plane of the equator passes through the centre of the sun, the attractive power of the sun acts only so as to draw the earth towards it, still parallel to itself, and without changing the position of its axis; a circumstance which happens only at the time of the equinoxes. In proportion as the earth recedes from those points, the sun also goes out of the plane of the equator, and approaches that of the one or other of the tropics; the semidiameter of the earth, then exposed to the sun, being unequal to what it was in the former case, the equator is more powerfully attracted than the rest of the globe, which causes some alteration in its position, and its inclination to the plane of the ecliptic: and as that part of the orbit, which is comprized between the autumnal and vernal equinox, is less than that which is comprized between the vernal and autumnal, it follows, that the irregularity caused by the sun, during his passage through the northern signs, is not entirely compensated by that which he causes during his passage through the southern signs; and that the parallelism of the terrestrial axis, and its inclination to the ecliptic, is thence a little altered.

The like effect which the sun produces on the earth, by his attraction, is also produced by the moon, which acts with greater force, in proportion as she is more distant from the equator. Now, at the time when her nodes agree with the equinoctial points, her greatest latitude is added to the greatest obliquity of the ecliptic. At this time therefore, the power which causes the irregularity in the position of the terrestrial axis, acts with the greatest force; and the revolution of the nodes of the moon being performed in 18 years 7 months, hence it happens that in this time the nodes will twice agree with the equinoctial points; and consequently, twice in that period, or once every 9 years, the earth's axis will be more influenced than at any other time.

That the moon has also a like motion, is shown by Newton, in the first book of the Principia; but he observes indeed that this motion must be very small, and scarcely sensible.

As to the history of the nutation, it seems there have been hints and suspicions of the existence of such a circumstance, ever since Newton's discovery of the system of the universal and mutual attraction of matter; some traces of which are found in his Principia, as above-mentioned.

We find too, that Flamsteed had hoped, about the year 1690, by means of the stars near his zenith, to determine the quantity of the nutation which ought to follow from the theory of Newton; but he gave up that project, because, says he, if this effect exists, it must remain insensible till we have instruments much longer than 7 feet, and more solid and better fixed than mine. Hist. Cœlest. vol. 3, pa. 113.

And Horrebow gives the following passage, extracted from the manuscripts of his master Roemer, who died in 1710, and whose observations he published in 1753, under the title of Basis Astronomiæ. By this paragraph it appears, that Roemer suspected also a nutation in the earth's axis, and had some hopes to give the theory of it: it runs thus; "Sed de altitudinibus non perinde certus reddebar, tàm ob refractionum varietatem quàm ob aliam nondum liquido perspectam causam; scilicet per hos duos annos, quemadmodum et alias, expertus sum esse quandam in declinationibus varietatem, quæ nec refractionibus nec parallaxibus tribui potest, sine dubio ad vacillationem aliquam poli terrestris referendam, cujus me verisimilem dare posse theoriam, observationibus munitam, spero." Basis Astronomiæ, 1735, pa. 66.

These ideas of a nutation would naturally present themselves to those who might perceive certain changes in the declinations of the stars; and we have seen that the first suspicions of Bradley in 1727, were that there was some nutation of the earth's axis which caused the star γ Draconis to appear at times more or less near the pole; but further observations obliged him to search another cause for the annual variations (art. ABERRATION); it was not till some years after that he discovered the second motion which we now treat of, properly called the nutation. See the art. STAR, where Bradley's discovery of it is given at length; to which may be further added the following summary.

For the better explaining the discovery of the nutation by Bradley, we must recur to the time when he observed the stars in discovering the aberration. He perceived in 1728, that the annual change of declination in the stars near the equinoctial colure, was greater than what ought to result from the annual precession of the equinoxes being supposed 50″, and calculated in the usual way; the star η Ursæ Majoris was in the month of September 1728, 20″ more south than the preceding year, which ought to have been only 18″; from whence it would follow that the precession of the equinoxes should be 55″¼ instead of 50″, without ascribing the difference between the 18 and 20″ to the instrument, because the stars about the solstitial colure did not give a like difference. Philos. Trans. vol. 35, pa. 659.

In general, the stars situated near the equinoctial colure had changed their declination about 2″ more than they ought by the mean precession of the equinoxes, the quantity of which is very well known, and the stars near the solstitial colure the same quantity less than they ought; but, Bradley adds, whether these small variations arise from some regular cause, or are occasioned by some change in the sector, I am not yet able to determine. Bradley therefore ardently continued his observations for determining the period and the law of these variations; for which purpose he resided almost continually at Wansted till 1732, when he was obliged to repair to Oxford to succeed Dr. Halley; he still however continued to observe with the same exactness all the circumstances of the changes of declination in a great number of stars. Each year he saw the periods of the aberration confirmed according to the rules he had lately discovered; but from year to year he found also other differences; the stars situated between the vernal equinox and the winter solstice approached nearer to the north pole, while the opposite ones receded further from it: he began therefore to suspect that the action of the moon on the elevated equatorial parts of the earth might cause a variation or libration in the earth's axis: his sector having been left fixed at Wansted, he often went there to make observations for many years, till the year 1747, when he was fully satisfied of the cause and effects, an account of which he then communicated to the world. Philos. Trans. vol. 45, an. 1748.

"On account of the inclination of the moon's orbit to the ecliptic," says Dr. Maskelyne, (Astronomical Observations 1776, pa. 2), "and the revolution of the nodes in antecedentia, which is performed in 18 years and 7 months, the part of the precession of the equinoxes, owing to her action, is not uniform; but subject to an equation, whose maximum is 18″: and the obliquity of the ecliptic is also subject to a periodical equation of 9″·55; being greater by 19·1″ when the moon's ascending node is in Aries, than when it is in Libra. Both these effects are represented together, by supposing the pole of the earth to describe the periphery of an ellipsis, in a retrograde manner, during each period of the moon's nodes, the greater axis, lying in the solstitial colure, being 19·1″, and the lesser axis, lying in the equinoctial colure, 14·2″; being to the greater, as the cosine of double the obliquity of the ecliptic to the cosine of the obliquity itself. This motion of the pole of the earth is called the nutation of the earth's axis, and was discovered by Dr. Bradley, by a series of observations of several stars made in the course of 20 years, from 1727 to 1747, being a continuation of those by which he had discovered the aberration of light. But the exact law of the motion of the earth's axis has been settled by the learned mathematicians Dalembert, Euler, and Simpson, from the principles of gravity. The equation hence arising in the place of a fixed star, whether in longitude, right ascension, or declination (for the latitudes are not affected by it) has been sometimes called nutation, and sometimes deviation." And again (says the doctor, pa. 8), "the above quantity 19·1″, of the greatest nutation of the earth's axis in the solstitial colure, is what I found from a scrupulous calculation of all Dr. Bradley's observations of γ Draconis, which he was pleased to communicate to me for that purpose. From a like examination of his observation of η Ursæ Majoris, I found the lesser axis of the ellipsis of nutation to be 14·1″, or only $\frac{1}{10}$th of a second less than what it should be from the observations of γ Draconis. But the result from the observations of γ Draconis is most to be depended on."

Mr. Machin, secretary of the Royal Society, to whom Bradley communicated his conjectures, soon perceived that it would be sufficient to explain, both the nutation and the change of the precession, to suppose that the pole of the earth described a small circle. He stated the diameter of this circle at 18″, and he supposed that it was described by the pole in the space of one revolution of the moon's nodes. But later calculations, and theory, have shown that the pole describes a small ellipsis, whose axes are 19·1″ and 14·2″, as above mentioned.

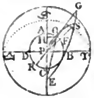
To show the agreement between the theory and observations, Bradley gives a great multitude of observations of a number of stars, taken in different positions; and out of more than 300 observations which he made, he found but 11 which were different from the mean by so much as 2″. And by the supposition of the elliptic rotation, the agreement of the theory with observation comes out still nearer.

By the observations of 1740 and 1741, the star η Ursæ Majoris appeared to be 3″ farther from the pole than it ought to be according to the observations of other years. Bradley thought this difference arose from some particular cause; which however was chiefly the fault of the circular hypothesis. He suspected also that the situation of the apogee of the moon might have some influence on the nutation. He invited therefore the mathematicians to calculate all these effects of attraction; which has been ably done by Dalembert, Euler, Walmesley, Simpson, and others; and the astronomers to continue to observe the positions of the smallest stars, as well as the largest, to discover the physical derangements which they may be subject to, and which had been observed in some of them.

Several effects arise from the nutation. The first of these, and that which is the most easily perceived, is the change in the obliquity of the ecliptic; the quantity of which ought to be varied from that cause by 18″ in about 9 years. Accordingly, the obliquity of the ecliptic was observed in 1764 to be 23° 28′ 15″, and in 1755 only 23° 28′ 5″: not only therefore had it not diminished by 8″, as it ought to have done according to the regular mean diminution of that obliquity; but it had been augmented by 10″; making together 18″, for the effect of the nutation in the 9 years.

The nutation changes equally the longitudes, the right-ascensions, and the declinations of the stars, as before observed; it is the latitudes only which it does not affect, because the ecliptic is immoveable in the theory of the nutation.

Dr. Bradley illustrates the foregoing theory of nutation in the following manner. Let P represent the mean place of the pole of the equator; about which point, as a centre, suppose the true pole to move in the small circle ABCD, whose diameter is 18″. Let E be the pole of the ecliptic, and EP be equal to the mean distance between the poles of the equator and ecliptic; and suppose the true pole of the equator to be at A, when the moon's ascending node is in the beginning of Aries; and at B, when



the node gets back to Capricorn; and at C, when the same node is in Libra: at which time the north pole of the equator being nearer the north pole of the ecliptic, by the whole diameter of the little circle AC, equal to 18″; the obliquity of the ecliptic will then be so much less than it was when the moon's ascending node was in Aries. The point P is supposed to move round E, with an equal retrograde motion, answerable to the mean precession arising from the joint actions of the sun and moon: while the true pole of the equator moves round P, in the circumference ABCD, with a retrograde motion likewise, in a period of the moon's nodes, or of 18 years and 7 months. By this means, when the moon's ascending node is in Aries, and the true pole of the equator at A, is moving from A towards B; it will approach the stars that come to the meridian with the sun about the vernal equinox, and recede from those that come with the sun near the autumnal equinox, faster than the mean pole P does. So that, while the moon's node goes back from Aries to Capricorn, the apparent precession will seem so much greater than the mean, as to cause the stars that lie in the equinoctial colure to have altered their declination 9″, in about 4 years and 8 months, more than the mean precession would do; and in the same time, the north pole of the equator will seem to have approached the stars that come to the meridian with the sun of our winter solstice about 9″, and to have receded as much from those that come with the sun at the summer solstice.

Thus the phenomena before recited are in general conformable to this hypothesis. But to be more particular; let S be the place of a star, PS the circle of declination passing through it, representing its distance from the mean pole, and ♈ PS its mean right-ascension. Thus if O and R be the points where the circle of declination cuts the little circle ABCD, the true pole will be nearest that star at O, and furthest from it at R; the whole difference amounting to 18″, or to the diameter of the little circle. As the true pole of the equator is supposed to be at A, when the moon's ascending node is in Aries; and at B, when that node gets back to Capricorn; and the angular motion of the true pole about P, is likewise supposed equal to that of the moon's node about E, or the pole of the ecliptic; since in these cases the true pole of the equator is 90 degrees before the moon's ascending node, it must be so in all others.

When the true pole is at A, it will be at the same distance from the stars that lie in the equinoctial colure, as the mean pole P is; and as the true pole recedes back from A towards B, it will approach the stars which lie in that part of the colure represented by P ♈, and recede from those that lie in P ♎; not indeed with an equable motion, but in the ratio of the sine of the distance of the moon's node from the beginning of Aries. For if the node be supposed to have gone backwards from Aries 30°, or to the beginning of Pisces, the point which represents the place of the true pole will, in the mean time, have moved in the little circle through an arc, as AO, of 30° likewise; and would therefore in effect have approached the stars that lie in the equinoctial colure P ♈, and have receded from those that lie in P ♎ by 4½ seconds, which is the sine of 30° to the radius AP. For if a perpendicular fall from O on AP, it may be conceived as part of a great circle, passing through the true pole and any star lying in the equinoctial colure. Now the same proportion that holds in these stars, will obtain likewise in all others; and from hence we may collect a general rule for finding how much nearer, or farther, any star is to, or from, the mean pole, in any given position of the moon's node.

For, if from the right-ascension of the star, we subtract the distance of the moon's ascending node from Aries; then radius will be to the sine of the remainder, as 9″ is to the number of seconds that the star is nearer to, or farther from, the true, than the mean pole.

This motion of the true pole, about the mean at P, will also produce a change in the right-ascension of the stars, and in the places of the equinoctial points, as well as in the obliquity of the ecliptic; and the quantity of the equations, in either of these cases, may be easily computed for any given position of the moon's nodes.

Dr. Bradley then proceeds to find the exact quantity of the mean precession of the equinoctial points, by comparing his own observations made at Greenwich, with those of Tycho Brahé and others; the mean of all which he states at 1 degree in 71¼ years, or 50⅓″ per year; in order to show the agreement of the foregoing hypothesis with the phenomena themselves, of the alterations in the polar distances of the stars; the conclusions from which approach as near to a coincidence as could be expected on the foregoing circular hypothesis, the diameter of which is 18″; instead of the more accurate quantity 19·1″, as deduced by Dr. Maskelyne, and the elliptic theory as determined by the mathematicians, in which the greater axis (19·1″) is to the less axis (14·2″), as the cosine of the greatest declination is to the cosine of double the same.

To give an idea now of the nutation of the stars, in longitude, right ascension, and declination; suppose the pole of the equator to be at any time in the point O, also S the place of any star, and OH perpendicular to AE: then, like as AE is the solstitial colure when the pole of the equator was at A, and the longitude of the star S equal to the angle AES; so OE is the solstitial colure when that pole is at O, and the longitude is then only the angle OES; less than before by the angle AEO, which therefore is the nutation in longitude: counting the longitudes from the solstitial instead of the equinoctial colure, from which they differ equally by 90 degrees, and therefore have the same difference AEO. Now the angle AEO will be as the line HO = sin. AO to radius PB = sin. AO × PB = sin. AO × 9″; therefore as EO : HO :: radius 1 : $\frac{HO}{EO} = \frac{\text{sin. AO} \times 9''}{\text{sin. } 23^\circ\ 28'} = \frac{\text{sin. node} \times 9''}{\text{sin. } 23^\circ\ 28'}$, since AO is equal to longitude of the moon's node. This expression therefore gives the nutation in longitude, supposing the maximum of nutation, with Bradley, to be 18″; and it is negative, or must be subtracted from the mean longitude of the stars, when the moon's node is in the first 6 signs of its longitude; but additive in the latter 6, to give the true apparent longitude.

This equation of the nutation in longitude is the same for all the stars; but that for the declination and right ascension is various for the different stars. In the foregoing figure, PS is the mean polar distance, or mean codeclination of the star S, when the true place of the pole is O; and so the aparent codeclination; also, the angle SPE is the mean right ascension, and SOE the apparent one, counted from the solstitial colure; consequently OPS or OPF the difference between the right ascension of the star and that of the pole, which is equal to the longitude of the node increased by 3 signs or 90 degrees; supposing OF to be a small arc perpendicular to the circle of declination PFS; then is SF = SO, and PF the nutation in declination, or the quantity the declination of the star has increased; but radius 1 : 9″ :: cosin. OPF : PF = 9″ × cos. OPF; so that the equation of declination will be found by multiplying 9″ by the sine of the star's right ascension diminished by the longitude of the node; for that angle is the complement of the angle SPO. This nutation in declination is to be added to the mean declination to give the apparent, when its argument does not exceed 6 signs; and to be subtracted in the latter 6 signs. But the contrary for the stars having south declination.

To calculate the nutation in right-ascension, we must find the difference between the angle SOE the apparent, and SPE the mean right-ascension, counted from the solstitial colure EO. Now the true right ascension SOE is equal to the difference between the two variable angles GOE and GOS; the former of which arises from the change of one of the variable circles EO, and depends only on the situation of the node or of that of the pole O; the latter GOS depends on the angle GPS, which is the difference between the right ascension of the star and the place of the pole O. Now in the spherical triangle GPE, which changes into GOE, the side GE and angle G remain constant, and the other parts are variable; hence therefore the small variation PO of the side next the constant angle G, is to the small variation of the angle opposite to the constant side GE, as the tangent of the side PE opposite to the constant angle, is to the sine of the angle GPE opposite to the constant side; that is, as tang. 23° 28′ : sin. OPE :: 9″ : $x = \frac{9'' \times \text{sin. OPE}}{\text{tang. } 23^\circ\ 28'}$, the difference between the angles GOE and GPE. This is the change which the nutation PO produces in the angle GPE, being the first part of the nutation sought, and is common to all the stars and planets. It is to be subtracted from the mean right-ascension in the first 6 signs of the longitude of the node, and added in the other six.

In like manner is found the change which the nutation produces in the other part of the right-ascension SPE, that is, in the angle SPG, which becomes SOG by the effect of the nutation. This small variation will be calculated from the same analogy, by means of the triangle SOG, in which the angle G is constant, as well as the side SG, while SP changes into SO. Hence therefore, tang. SP : sin. SPG :: 9″ : variation of SPG, that is, the cotangent of the declination is to the cosine of the distance between the star and the node, as 9″ are to the quantity the angle SPG varies in becoming the angle SOG, being the second part of the nutation in right-ascension; and if there be taken for the argument, the right-ascension of the star minus the longitude of the node, the equation will be subtractive in the first and last quadrant of the argument, and additive in the 2d and 3d, or from 3 to 9 signs. But the contrary for stars having south declination.

This second part of the nutation in right-ascension affects the return of the sun to the meridian, and therefore it must be taken into the account in computing the equation of time. But the former part of the nutation does not enter into that computation; because it only changes the place of the equinox, without changing the point of the equator to which a star corresponds, and consequently without altering the duration of the returns to the meridian.

All these calculations of the nutation, above explained, are upon Machin's hypothesis, that the pole describes a circle; however Bradley himself remarked that some of his observations differed too much from that theory, and that such observations were found to agree better with theory, by supposing that the pole, instead of the circle, describes an ellipse, having its less axis DB = 16″ in the equinoctial colure, and the greater axis AC = 18″, lying in the solstitial colure. But as even this correction was not sufficient to cause all the inequalities to disappear entirely, Dr. Bradley referred the determination of the point to theoretical and physical investigation. Accordingly several mathematicians undertook the task, and particularly Dalembert, in his Recherches sur la Précession des Equinoxes, where he determines that the pole really describes an ellipse, and that narrower than the one assumed above by Bradley, the greater axis being to the less, as the cosine of 23° 28′ to the cosine of double the same. And as Dr. Maskelyne found, from a more accurate reduction of Bradley's observations, that the maximum of the nutation gives 19·1″ for the greater axis, therefore the above proportion gives 14·2″ for the less axis of it; and according to these data, the theory and observations are now found to agree very near together.

See Lalande's Astron. vol. 3, art. 2874 &c, where he makes the corrections for the ellipse. He observes however that by the circular hypothesis alone, the computations may be performed as accurately as the observations can be made; and he concludes with some corrections and rules for computing the nutation in the elliptic theory.

The following set of general tables very readily give the effect of nutation on the elliptical hypothesis; they were calculated by the late M. Lambert, and are taken from the Connoissance des Temps for the year 1788.

General Tables for Nutation in the Ellipse.

This table is constructed from Dalembert's ellipse, whose semi-axes are 9″ and 6·7″; half their sum and half their diff. are 7·85″ and 1·15″, as in the following formulæ. The number 15·43″, in the 2d formula, is $= 6·7'' \times$ cotangent of the ellipse's obliquity. If the semi-axes be 9·55″ and 7·1″, the formulæ will give the nutation as in Dr. Maskelyne's Tables, of 1776.

The Use of the Tables.

The right-ascension of a star minus the moon's mean longitude, gives the argument of the first of these three tables. The sum of the same two quantities gives the argument of the 2d table. Then the sum or the difference of the quantities found with these two arguments, will give the correction to be applied to the mean declination of the star, if it is north declination; but if it is southern, the signs + or − are to be changed into − and +.

From each of those two arguments for the declination subtracting 3 signs, or 90°, gives the arguments for correcting the right-ascension; the sum or difference of the quantities found, with these two arguments, in tables 1 and 2, is to be multiplied by the tangent of the star's declination, and to the product is to be added the quantity taken out of table 3, the argument of which is the mean longitude of the moon's ascending node: when the declination of the star is south, the tangent will be negative.

Example, To find the nutation in right-ascension and declin. for the star α Aquilæ, the 1st of July, 1788.

Right-ascension of the star	9ˢ	25°	7′	
Long. of the moon's node	8	15	40	
Diff. being argument 1,	1	9	27	+ 4″99
Sum, argument 2, - -	6	10	47	− 0·22
Correction of the declination - - -				+ 4·77

The above two arguments being each diminished by 3 signs, give,

Argument 1 - - - - - - -	10ˢ 9° 27′	− 6″06
Argument 2 - - - - - - -	3 10 47	+ 1·13
		− 4·93
Declin. of star north, its tangent - - -		0·146
The product is - - - - - - - -		− 0·72
Long. of the ☾'s node, argum. 3 - -		+ 14·94
Correction of right-ascension - - -		+ 14·22

In general, let ☊ denote the longitude of the moon's ascending node; r the right-ascension of a star or planet; d its declination; the nutation in declination and right-ascension will be expressed by the two following formulæ; viz, the nutation in declination

$= 7''\cdot85 \times \sin.\ (r - ☊) + 1''\cdot15 \times \sin.\ (r + ☊)$;

and the nutation in right-ascension

$= [7''\cdot85 \times \sin.\ (r - ☊ - 90^\circ) + 1''\cdot15 \times \sin.\ (r + ☊ - 90^\circ)] \times \text{tang.}\ d - 15''\cdot43 \times \sin.\ ☊$.

For the mathematical investigation of the effects of universal attraction, in producing the nutation, &c, see d'Alembert's Recherches sur la Precession des Equinoxes; Silvabelle's Treatise on the Precession of the Equinoxes &c, in the Philos. Trans. an. 1754, pa. 385; Walmesley's treatise de Præcessione Equinoctiorum et Axis Terræ Nutatione, in the Philos. Trans. an. 1756, pa. 700; Simpson's Miscellaneous Tracts, pa. 1; and other authors.

O.

OBELISK, a kind of quadrangular pyramid, very tall and slender, raised as an ornament in some public place, or to serve as a memorial of some remarkable transaction.

OBJECT, something presented to the mind, by sensation, or by imagination; or something that affects us by its presence, that affects the eye, ear, or some other of the organs of sense.—The objects of the eye, or vision, are painted on the retina; though not there erect, but inverted, according to the laws of optics. This is easily shown from Descartes's experiment, of laying bare the vitreous humour on the back part of the eye, and putting over it a bit of white paper, or the skin of an egg, and then placing the fore part of the eye to the hole of a darkened room. By this means there is obtained a pretty landscape of the external objects, painted invertedly on the back of the eye. In this case, how the objects thus painted invertedly should be seen erect, is matter of controversy.

OBJECT-*Glass*, of a telescope or microscope, is the glass placed at the end of the tube which is next or towards the object to be viewed.

To prove the goodness and regularity of an object-glass; describe two concentric circles on a piece of paper, the one having its diameter the same with the breadth of the object-glass, and the other half that diameter; divide the smaller circumference into 6 equal parts, pricking the points of division through with a fine needle; cover one side of the glass with this paper, and, exposing it to the sun, receive the rays through these 6 holes upon a plane; then by moving the plane nearer to or farther from the glass, it will be found whether the six rays unite exactly together at any distance from the glass; if they do, it is a proof of the regularity and just form of the glass; and the said distance is also its focal distance.—Another way of proving the accuracy of an object-glass, is by placing it in a tube, and trying it with small eye-glasses, at several distant objects; for that object-glass is always the best, which represents objects the brightest and most distinct, and which bears the greatest aperture, and the most convex and concave eye-glasses, without colouring or haziness.

A circular object-glass is said to be truly centred, when the centre of its circumference falls exactly in the axis of the glass; and to be ill centred, when it falls out of the axis. To prove whether object-glasses be well centred, hold the glass at a proper distance from the eye, and observe the two reflected images of a candle, varying the distance till the two images unite, which is the true centre point: then if this fall in the middle, or central point of the glass, it is a proof of its being truly centred.

As object-glasses are commonly included in cells that screw upon the end of the tube of a telescope, it may be proved whether they be well centred, by fixing the tube, and observing while the cell is unscrewed, whether the cross-hairs keep fixed upon the same lines of an object seen through the telescope.—For various methods of finding the true centre of an object-glass, see Smith's Optics, book 3, chap. 3; also the Philos. Trans. vol. 48, pa. 177.

OBJECTIVE *Line*, in Perspective, is any line drawn on the geometrical plane, whose representation is sought for in a draught or picture.

OBJECTIVE *Plane*, in Perspective, is any plane situated in the horizontal plane, whose perspective representation is required.

OBLATE, flatted, or shortened; as an oblate spheroid, having its axis shorter than its middle diameter; being formed by the rotation of an ellipse about the shorter axis.

OBLATENESS, of the earth, the flatness about the poles, or the diminution of the polar axis in respect of the equatorial. The ratio of these two axes has been determined in various ways; sometimes by the measures of different degrees of latitude, or of longitude, and sometimes by the length of pendulums vibrating seconds in different latitudes, &c; the results of all which, as well as accounts of the means of determining them, see under the articles EARTH and DEGREE. To what is there said, may be added the following, from An Account of the Experiments made in Russia concerning the Length of a Pendulum which swings Seconds, by Mr. Krafft, contained in the 6th and 7th volumes of the New Petersburg Transactions, for the years 1790 and 1793. These experiments were made at different times, and in various parts of the Russian empire: Mr. Krafft has collected and compared them, with a view to investigate the consequences that might thence be deduced; and from the whole he concludes, that the length p of a pendulum, which swings seconds in any given latitude l, and in a temperature of 10 degrees of Reaumur's thermometer, may be determined by the following equation, in lines of a French foot: viz,

$$p = 439\cdot178 + 2\cdot321 \text{ sine}^2 l.$$

This expression agrees, very nearly, not only with all the experiments made on the pendulum in Russia, but also with those of Mr. Graham, and those of Mr. Lyons in 79° 50′ north latitude, where he found its length to be 441·38 lines.—It also shows the augmentation of gravity from the equator to the parallel of a given latitude l: for, putting g for the gravity under the equator, G for that under the pole, and z for that under the latitude l; Mr. Krafft finds $z = (1 + 0·0052848 \text{ sine}^2 l) \times g$; and consequently $G = 1·0052848\, g$.

From this proportion of gravity under different latitudes, Mr. Krafft deduces, that on the hypothesis of the earth's being a homogeneous ellipsoid, its oblateness must be $\frac{1}{180}$; instead of $\frac{1}{230}$, which ought to be the result of this hypothesis; but on adopting the supposition that the earth is a heterogeneous ellipsoid, he finds its oblateness, as deduced from these experiments, to be $\frac{1}{267}$; which agrees nearly with that resulting from the measurement of degrees of the meridian.—This confirms an observation of M. Laplace, that, if the hypothesis of the earth's homogeneity be given up, then will theory, the measurement of degrees of latitude, and experiments with the pendulum, all agree in their result with respect to the oblateness of the earth.

OBLIQUE, aslant, indirect, or deviating from the perpendicular. As,

OBLIQUE *Angle*, one that is not a right angle, but either greater or less than this, being either obtuse or acute.

OBLIQUE-*angled Triangle*, that whose angles are all oblique.

OBLIQUE *Ascension*, is that point of the equinoctial which rises with the centre of the sun, or star; or any other point of the heavens, in an oblique sphere.

OBLIQUE *Circle*, in the stereographic projection, is any circle that is oblique to the plane of projection.

OBLIQUE *Descension*, that point of the equinoctial which sets with the centre of the sun, or star, or other point of the heavens in an oblique sphere.

OBLIQUE *Direction*, that which is not perpendicular to a line or plane.

OBLIQUE *Force*, or Percussion, or Power, or Stroke, is that made in a direction oblique to a body or plane. It is demonstrated that the effect of such oblique force &c, upon the body, is to an equal perpendicular one, as the sine of the angle of incidence is to radius.

OBLIQUE *Line*, that which makes an oblique angle with some other line.

OBLIQUE *Planes*, in Dialling, are such as recline from the zenith, or incline towards the horizon.

OBLIQUE *Projection*, is that where a body is projected or impelled in a line of direction that makes an oblique angle with the horizontal line.

OBLIQUE *Sailing*, in Navigation, is that part which includes the application and calculation of oblique-angled triangles.

OBLIQUE *Sphere*, in Geography, is that in which the axis is oblique to the horizon of a place.—In this sphere, the equator and parallels of declination cut the horizon obliquely. And it is this obliquity that occasions the inequality of days and nights, and the variation of the seasons. See SPHERE.

OBLIQUITY, that which denotes a thing oblique.

OBLIQUITY *of the Ecliptic*, is the angle which the ecliptic makes with the equator. See ECLIPTIC.

OBLONG, sometimes means any figure that is longer than it is broad; but more properly it denotes a rectangle, or a right-angled parallelogram, whose length exceeds its breadth.

OBLONG, is also used for the quality or species of a figure that is longer than it is broad: as an oblong spheroid, formed by an ellipse revolved about its longer or transverse axis; in contradistinction from the oblate spheroid, or that which is flatted at its poles, being generated by the revolution of the ellipse about its conjugate or shorter axis.

OBSCURA *Camera*. See CAMERA *Obscura*.

OBSCURA *Clara*. See CLARA *Obscura*.

OBSERVATION, in Astronomy and Navigation, is the observing with an instrument some celestial phenomenon; as, the altitude of the sun, moon, or stars, or their distances asunder, &c. But by this term the seamen commonly mean only the taking the meridian altitudes, in order to find the latitude. And the finding the latitude from such observed altitude, they call Working an Observation.

OBSERVATORY, a place destined for observing the heavenly bodies; or a building, usually erected on some eminence, for making astronomical observations.

Most nations, at almost all times, have had their observatories, either public or private ones, and in various degrees of perfection. A description of a great many of them may be seen in a dissertation of Weidler's, De præsenti Specularum Astronomicarum Statu, printed in 1727, and in different articles of his History of Astronomy, printed in 1741, viz, pa. 86 &c; as also in Lalande's Astronomy, the preface pa. 34; also in Bailly's astronomical works, and elsewhere.

As navigation essentially depends on the determinations made in observatories, such establishments have been considered of great national importance, especially in maritime states; and hence they have been liberally endowed by different governments. Even private observatories have been, in many places, erected at considerable expense; the number of which has been greatly increased of late years; a circumstance which, while it marks the progress of science, does honour to the age in which we live.

FIXED observatories are those where instruments are fixed in the meridian, by which, with the aid of astronomical clocks, the right-ascensions and declinations of the heavenly bodies are determined; and motion, time, and space made to measure each other. Such buildings and apparatus only are called *regular* observatories, though very useful operations are sometimes performed, and important discoveries made, where no instruments are fixed in the meridian.

History of Observatories.

All nations, where astronomy has been cultivated, boast of having had observatories at an early period; though ancient history affords but little information on the subject. It was not indeed, until considerable progress had been made, both in astronomy and the mechanical arts, that successful attempts were made, either in constructing instruments, or erecting edifices for astronomical purposes. The first observatories of man were the fields or hills, and his eyes his instruments; and his progress by these aids alone was astonishing. The instruments of ancient astronomers were very large, and of rude construction; mostly of wood, and some of stone. They consisted chiefly of gnomons, dials, and astrolabes; and long tubes, like telescopes, were used to assist the sight. For the same purpose deep wells were also sunk in dry places, from the bottom of which the stars might be seen in the day-time. Most buildings for astronomical observations were of great altitude, and chiefly erected in very high situations.

In Chaldæa, a country celebrated in the early annals of astronomy, the lofty temple of Belus, or tower of Babel, was used as an observatory. And in Egypt, the famous tomb of Osymandias was applied to the same purpose. This building, it has been said, contained a golden or gilded circle, for celestial observations, which was 365 cubits in circumference, and one cubit in thickness.

The pyramids of Egypt have also been supposed intended for observatories; and in support of this opinion it is argued, that they were built to face the four cardinal points. The great height of these pyramids is to be sure favourable for celestial observations, whether they be used as gnomons, or for the purposes of astrology, a favourite study in those times, and which chiefly required an accurate view of the rising and setting of stars. It is indeed certain that practical astronomy was much improved in Egypt, particularly in the famous school of Alexandria, where an observatory was built 300 years before the Christian era, and continued for more than five centuries under a succession of celebrated names, such as Aristellus, Hipparchus, Ptolemy, &c.

The Chinese and Gentoo nations appear to have made a very early progress, both in the theory and practice of astronomy. Those people have traditions and vestiges of ancient observatories, on which ingenious disquisitions may be seen in Bailly's History of Ancient Astronomy, and in the Asiatic Researches, by Sir Wm. Jones, by Messrs. Hunter, Bentley, Colebrooke, Sir Robert Barker, and others.

The Hindu institutions, five in number, were constructed nearly at the same period, about 250 years ago. They were built by order of the emperor Mahommed Shah, with a view to reform the calendar by means of astronomical observations; and he chose for his chief astronomer Jeysing, or Jayasinha, the rajah of Ambhere. These observatories were built at Delhi, Benares, Matra, Oujein, and Suvai Jeypoor, and all under the direction of Jeysing. The observatory at Benares may be seen minutely described, by Sir Rob. Barker, in the Philos. Trans. for 1777, where he has given several plates of views, both of the buildings and instruments. And as all the other observatories were built and furnished nearly on the same plan, his description may be deemed sufficient for the whole. The instruments are quadrants and gnomons of enormous size, built of stone, of most excellent masonry and construction, and very accurately divided and cut, into 90 degrees and other subdivisions. The quadrants are of different sizes, some as much as 20 feet radius. The account of the Benares observatory is furthur illustrated by Wm. Hunter, esq. in a very elaborate article in the Asiatic Researches, vol. 5; in which he gives a full and particular description of the other four Hindu observatories.

At Pekin, in China, an imperial observatory was built in the 13th century, on the city walls. And in 1669, father Verbiest, a missionary jesuit, having been made president of the tribunal of the mathematics there, and chief observer, obtained permission from the emperor Cam-hi, to furnish it with instruments, a catalogue of which may be seen in Duhalde's Description of China.

Other observatories were afterwards built in China by the French missionaries, and by the Portuguese jesuits, who very much distinguished themselves by their improvements in astronomy. The instruments of the Pekin observatory are described as very large; but the divisions less accurate, and the contrivance less commodious, than the instruments made at that period in Europe. The chief were, a sextant 8 feet radius, a quadrant 6 feet radius, an azimuthal horizon; also a celestial globe, an armillary zodiacal sphere, each 6 feet diameter.

It is said that Copernicus, in 1540, was the first European who set an instrument in the meridian. But it is stated by Weidler, Bailly, and Costard, that the first regular observatory in Europe was erected at Cassel in 1561, by William, landgrave of Hesse, who furnished it with the best instruments the age could afford; and where it is said he made very accurate observations, in concert with his friend and correspondent, Tycho Brahé, who was then rising into great fame.

The next observatory in Europe, that deserves particular notice, was that of Tycho Brahé himself, which it seems owed its origin to a very extraordinary cause, the appearance of a new star of the first magnitude, in the constellation Cassiopeia. It was seen by different astronomers about the 10th Nov. 1572, when it seemed to break forth instantaneously, which added to the great astonishment that universally prevailed on the occasion. It was brighter than Jupiter or Venus, when nearest to the earth, and was visible to the naked eye at mid-day. After a short time it gradually declined, and in 16 months totally disappeared. Tycho Brahé was so impressed with this phenomenon, that he formed the resolution of making a new and accurate catalogue of all the stars, as there had been nothing of the kind regularly performed since the days of Hipparchus, who, it is remarkable, had been stimulated to the like undertaking by a similar cause, that is, by the sudden appearance and disappearance of a new star.

For this purpose, Tycho Brahé first proposed to settle at Basle, which afforded at once a pure atmosphere, and a ready communication with the learned men of Germany, Italy, and France. But the landgrave of Hesse wrote to Frederick the 2nd, king of Denmark, entreating him to encourage the astronomer to remain in his own country. In consequence the king assigned to him the small but fruitful island Huen, or Heven, in the Sound, as a fit situation for an observatory, and conferred on him also other princely grants and immunities: his majesty besides undertook to defray the charge of building and furnishing the observatory there, without any limitation of expense; a munificence which has immortalized his name. The first stone of the observatory was laid the 8th of August 1576, and the place was called Uranibourg, or the Heavenly City. It was a building of 60 feet square, and 70 feet in height, with four towers, all contrived for astronomical purposes. It was furnished with a noble collection of instruments, many of them invented by the astronomer himself. He had numerous assistants, whom he supported and instructed. Among his instruments was a celestial globe, of 6 feet diameter, said to have cost 1000*l.* It was after his death carried to Prague; next to Neis, and lastly to Copenhagen, where it was burnt in the great conflagration which happened there in 1728. Many of the instruments of this great astronomer were long preserved, but have been gradually lost; and his favourite city Uranibourg, which, in his time, was visited by kings and princes, has been long a heap of ruins, though occasionally visited by the learned. His celebrated sextant has been consecrated in the heavens as a constellation, under the breast of the Lion: on large globes and atlases it is marked *Sextans Uraniæ*, but on common ones only *Sextans*.

We shall now proceed to notice some observatories of a more modern date, beginning with those of France.

French Observatories.

The Royal, or now Imperial, Observatory of Paris, was built in 1667. It is 160 feet in front by 120 feet in breadth, and 90 feet high. Its vaults are 90 feet deep; so that it is 180 feet from top to bottom. A particular description of the building is given by Blondel, and the arrangement and disposition of the instruments in Bernoulli's Lettres Astronomiques, also in Lalande's Astronomie, and in Monnier's Histoire Celeste.

Besides the above building, new rooms have been constructed, close by the side of the observatory, where a large transit instrument and circle, by Ramsden, have been set up. In 1788 new vaults were made, and also a small observatory erected on the top of the building, which commands an extensive view of the horizon; and the king (Louis the 16th) established three observers here, that the course of observations might as little as possible be interrupted.

The following account of other observatories at Paris, given by Lalande in 1792, is worthy of notice here, as interesting in the history of practical astronomy.

The astronomers of the Academy had besides several private observatories erected in different parts of Paris, as the royal observatory was not sufficient for all. That of Monnier has been, from the year 1742, in the garden of the Capuchins. That of the Marine, which Joseph de l'Isle used in 1748 at the Hotel de Clugny, occupied by M. Messier. That of Lacaille still exists in the Mazarin-college. That of the palace of Luxembourg is above the Port Royal. Joseph de Lisle observed there, and Lalande likewise occupied it for some time. That of M. Pingré at the abbey of St. Généviève was built in 1756. There is one of Cagnoli's rue de Richlieu, which this able astronomer built at his own expense in 1785, when he still resided at Paris.

The observatory of the military school, built for M. Jeaurat in 1768, was occupied afterwards by M. d'Agelet. The late M. Bergeret, receiver-general of finances, constructed in 1774 a large mural quadrant of 8 English feet radius, the last and the best instrument made by the celebrated Bird. This instrument was obtained by the military academy, as well as an excellent transit instrument, and a parallactic telescope. M. d'Agelet made a great number of observations there from 1778 to 1785, when he left it to make a voyage round the world with La Perouse. In 1788, the changes made in the military school occasioned the demolition of this observatory; but it has been rebuilt, a little more to the west, with all necessary attention and expense, so that it is the most complete observatory at Paris. Lalande, having received the direction of it, began in 1789 to make a series of observations. M. le François Lalande, his relation and pupil, has also made a prodigious number of observations; and they observed, in 1791, more than ten thousand northern stars, with excellent instruments. An observatory was built in 1775, at the Royal-college, for the use of the professor of astronomy of this celebrated school. M. Geoffroy d'Assy built, in 1788, an observatory at his house, rue de Paradis, which was used by M. Delambre.

Such was the state of observatories at Paris in 1792. At present (1813) Delambre is the chief of the imperial university. Messier and Biot succeeded him at the Royal-college, now the College de France. Burckhardt is astronomer at the military school; Lefrançois Lalande resides at the Place de Cambray; and Bouvard superintends the imperial observatory, assisted by Arago.

It may be noticed here, that the famous mural quadrant, with which Lalande and his relation determined the position of a great number of stars, as above-mentioned, has been consecrated in the heavens as a constellation, and is placed between Hercules, the Serpent, and Boötes. It is marked Quadrans Muralis, and contains 40 stars.

The following were the other observatories established in different parts of France, as stated by Lalande.

The *Marseilles* observatory, which has been rendered famous by the observations of Sylvabelle.

At *Toulouse*, the observatory of M. Darquier has been made sacred by the zeal and abilities of this learned man. Observatories have also been built in the same city by M. Garipuy and M. Bonrepos. Here astronomy has been more successfully cultivated than in any other provincial city in France. The principal observatory is at present (1813) under the superintendence of M. Vidal.

At *Lyons*, the College observatory, which was built by father St. Bonnet, is a very fine edifice, on an elevated situation.

At *Dijon*, M. Necker, about the year 1780, converted the tower of the king's lodge to an observatory, and the abbé Bertrand has made very accurate observations there.

At *Montpellier* there has long been an observatory erected on one of the towers of the city; where M. Ratte and Poitevin have distinguished themselves as able astronomers.

At *Beziers*, the bishop's tower was converted to an observatory, where some interesting observations have been made by M. Bouillet, particularly on Saturn's ring.

At *Avignon*, an observatory was built by father Bonfa so early as 1683; and it has been since occupied by a succession of learned ecclesiastics, who have distinguished themselves in practical astronomy.

At *Strasburg*, Brackenhoffer, professor of mathematics, had an observatory over the gates of the city, and he has been succeeded by Herzenschneider in 1790.

At *Bourdeaux* is an observatory 75 feet high, and 20 feet square. It is situated in the finest part of Tournay, in latitude 45°. Here M. Turgot procured a complete set of observations to be made on the length of a pendulum vibrating seconds; upon which father Boscovich has made an interesting memoir.

At *Brest* a small observatory was built for the naval academy, and plans have been set on foot for erecting a more considerable edifice.

At *Rouen* there is an observatory belonging to M. Bouin, in which he has made many good observations.

At *Montauban* the duc de la Chapelle founded an observatory, where he himself has made many accurate and interesting observations, particularly of the transit of Venus over the sun in 1769.

German Observatories.

In Germany a great number of observatories have been established, and that country has produced also several very able astronomers.

At *Berlin*, Frederic the 1st, king of Prussia, founded an observatory in 1711, under the direction of Leibnitz, who was president of the Academy of Sciences there. It is a large square tower, very steady. Here Grischow and Kies made various observations: and Lalande also observed here about the year 1752, where, he says, he raised enormous pillars, to which he attached the mural quadrants, north and south. (Memoires de l'Academie, 1751 and 1752.) King Frederic the 2d added a very fine building to it, where the Academy of Sciences of Prussia has held its assemblies. M. Bode has been many years the astronomer-royal there, and has distinguished himself both as an accurate observer, and as the publisher of the most complete celestial atlas extant, entitled Uranographia, which is accompanied with a well arranged catalogue of the stars, and an interesting history of the constellations.

At *Vienna*, the empress Maria Theresa built an observatory in the year 1755 for the university, and furnished it with many superb instruments. There is also one belonging to the academical college, which was built and endowed by the Jesuits in 1735, and it is also furnished with very fine instruments, chiefly made by English artists, and a succession of very learned men have observed there. The reputation of the university observatory was maintained for many years by the abbé Maximilian Hell, who conducted the Vienna Ephemeris, and the work is now continued by M. Treisneckir, his successor.

At *Gottingen* there is an observatory memorable by the labours of Tobias Mayer, and by those more recently of Harding, who discovered the planet Juno in 1804.

At *Nuremberg* an observatory was built so early as the year 1678, and another in 1692. M. Zimmert and M. Wuzzelbau have distinguished themselves here both as able authors and accurate observers.

At *Cassel* an observatory was built, in 1714, by Charles I, landgrave of Hesse, heir to the territories and taste of the celebrated William, the early friend and fellow-labourer of Tycho Brahé.

In 1740 an observatory was built at *Griessen*; and in 1768 at Ourtsbourg, in Franconia. In 1788 one was built at Leipsic, on an old tower of great firmness. Observatories have been also erected and supported with great credit at Manheim, Cremsmunster, Lambach, Polling, Prague, and Gratz.

At *Bremen* there is an observatory belonging to Dr. Olbers, an eminent physician, who has rendered his name immortal by the discovery of the two new planets, Pallas and Vesta.

At *Lilienthal*, near Bremen, M. Schroeter, governor of the district, erected an observatory about the year 1786, and furnished it with excellent instruments. He is highly celebrated as an accurate and interesting observer, particularly of the surfaces and rotations of the planets and the moon. He approaches nearer than any other astronomer to Dr. Herschel in telescopic discoveries.

At *Seeberg*, near Gotha, a considerable observatory was built, in the year 1788, by the duke of Saxe Gotha, and he appointed M. Zach, now baron Zach, the superintendant, who has highly distinguished himself as a profound and accurate astronomer. In 1798 he was visited by Lalande, when, according to Voiron (Histoire de l'Astronomie, pa. 369), all the great astronomers of Germany met at Gotha, to see the patriarch of astronomy, and to pay him their homage. This observatory is reckoned one of the most beautiful and complete in Europe; it is situated on a fine elevation, about a league from the town. There is here a large transit, with two murals of 8 feet radius, and a circle of 8 feetdiameter, all by Ramsden and his successor Berge.

At *Brunswick* there is an observatory belonging to Dr. Gauss, well known by his determinations of the orbits of the new planets, and other important labours.

In *Hungary* there are observatories at Buda, Tyrnau, and Erlau. Similar establishments are also at *Greiffswalde* in Pomerania, and at *Mittau* in Courland.

In *Poland* there is an observatory at *Cracow*, and another at *Wilna*: the latter was built and richly endowed by the countess Puzynina, a lady of fine genius as well as liberality. It was finished in 1753, and the instruments with which it is furnished were of great variety and value. In 1765 the king of Poland, by letters patent, gave it the title of Royal observatory, and appointed the learned Jesuit Poczobut astronomer-royal, who, in 1788, added another observatory, which he furnished with new instruments, chiefly made by Ramsden.

In *Sweden* observatories have been built at Stockholm and Upsal: that at Stockholm was founded in 1746, by the Academy of Sciences. In 1753, Wargentin was appointed astronomer to it, and in 1783 he was succeeded by Nicander. This observatory is situated on a hill north of the town, and contains a good collection of instruments, all made by English artists.

The observatory at *Upsal* was built and endowed in 1739 by the king of Sweden: it was first superintended by the celebrated Celsius, who has been followed by a succession of able astronomers, particularly Hooker and Wargentin. The latter is well known as the author of the tables of Jupiter's satellites.

At *Dantzic* there was an old observatory, celebrated as having been used by Hevelius, who has given a full description of it in his work, entitled Machina Cœlestis. A new observatory was also built in that city in the year 1778, which is at present superintended by Dr. Wolff.

At *Copenhagen* the famous astronomical tower was finished in 1656. It was built by King Christian IV, at the recommendation of Longomontanus, and has been for many years under the management of Mr. Bugge, who is celebrated as a very able astronomer. In his collection of observatories, he states that the kings of Denmark had established observatories in Norway, Iceland, and Greenland.

In *Holland* attention was paid to practical astronomy while it was a maritime state; but the science has of late been much neglected. In 1690 an observatory was erected on the college of the university; and at Utrecht an ancient tower was, in 1726, converted into an observatory. Here the celebrated Van Musschenbroek observed for many years with great accuracy, and he was succeeded by M. Hennert.

In *Spain* observatories have been built at Cadiz, Madrid, Seville, and Carthagena. The observations made at Cadiz (at the Marine academy) by Miguel and Varilla, have been published in two volumes, which also contain a catalogue of the instruments of the observatory, chiefly constructed by French artists; and hence the observatories of Spain differ very little from those of France. Of late years, however, English instruments have been introduced there.

At *Lisbon*, in 1728, King John the 5th had an observatory erected at his palace, which was well furnished, and accurate observations have been made there by the Jesuits, who also erected an observatory at their own college of St. Anthony, where father Carbon, in 1726, made good observations on the satellites of Jupiter. See Phil. Trans. vol. 35, pa. 408.

In 1787, a royal observatory was constructed at the Chateau de St. George, in Lisbon, which was superintended by M. Custodio Gomez. There is also one at *Coimbra*, which contains a fine equatorial by Troughton.

At *Petersburg* an observatory was built, in 1725, by the czar Peter, who showed great zeal for science in general, and particularly for astronomy. When he was in England, some years before that period, he visited the Royal Observatory at Greenwich, where he examined both the building and the instruments with very great attention. The observatory which he afterwards built is one of the most magnificent in Europe. It is 130 feet high, with three stories, all fit for astronomical purposes. M. Delisle has made, according to Lalande, a great number of excellent observations here, which are preserved in manuscript in the marine depôt.

At *Moscow* an observatory was built a few years ago, and furnished with some excellent English instruments, chiefly by Cary; but it is probable that they have been destroyed in the late conflagration of that city.

In *Italy*, practical astronomy has been cultivated with much assiduity and success during the last century, chiefly by ecclesiastics, and particularly by the Jesuits.

At *Rome*, cardinal Zelada constructed, at his own expense, on the southern part of the Roman college, a very fine observatory, with the large sector of father Boscovich, and other instruments by Ramsden and Dollond. The abbé Calandrelli observed here with great attention and accuracy for many years. Other buildings of a similar description have been erected in different parts of Rome.

At *Bologna* a magnificent observatory was built in 1714, in the palace of the Institute, by the munificence of the celebrated count Marsigli; and pope Benedict 14 gave afterwards a large sum of money towards the purchase of instruments. Here a succession of able astronomers have observed, among whom may be mentioned Manfredi, Zanotti, Canterzani, &c.

At *Pisa* the observatory is in the form of a tower. It was built in 1730, at the expense of the university, and supplied with superb apparatus made by Sisson, Short, Graham, &c. Perelli observed here for many years, and had for a successor M. Slope, who published an excellent collection of observations in 1789.

At *Milan* there is an observatory, which is reckoned one of the most useful in Italy. It was built in 1765, at the cost of the college of the Jesuits, chiefly through the zeal of father Pallavicini, and under the direction of father Boscovich, who also contributed liberally to the expense. The instruments have been made with great care by the principal French and English artists. Among the observers may be also mentioned Reggio, Oriani, and Cesaris.

At *Florence*, father Ximenes erected an observatory at the college of Jesuits, which contains a quadrant by Toscanelli, larger than any other known, with which he made observations to prove the secular diminution of the obliquity of the ecliptic. At his death he bequeathed the whole to the college. In 1772 the grand duke Leopold built an observatory, which M. Fontana superintended, and in 1786 several fine instruments by Ramsden were added to it.

At *Turin* father Beccaria erected a small observatory; but in 1790 a large one was built at a very considerable expense, by the king of Sardinia, at the Royal College of Nobles, and the direction of it given to the abbé Caluso.

At *Venice* an observatory was constructed by father Panigai, and a small one near the town by M. Miotti. One was also built at *Parma* by father Belgrado, and another at *Brescia* by father Cavalli.

At *Verona*, Cagnoli, eminent both as a mathematician and astronomer, erected an observatory at his own expense, in 1787, and placed in it the best instruments, with which he has made very accurate and important observations, particularly on the precession of the equinoxes, and on the places of 473 northern stars, and 26 southern, of which he has made a catalogue. In these determinations he has been perhaps more attentive than any other astronomer to the minute changes of refraction, and to the aberration of light.

At *Padua* there is an observatory, which in 1778 was furnished with instruments, chiefly made by Ramsden. It has been many years under the direction of M. Toaldo, who has published several useful works, especially a treatise on meteorology, which gained him the prize at the academy of Montpellier.

In some of the islands of the Mediterranean observatories have also been established. We shall, however, notice only those of *Malta* and *Sicily*.

In 1783, the grand-master Emmanuel de Rohan, an amateur and enlightened protector of science, invited to Malta chevalier d'Angos, a skilful astronomer, who converted a tower of the palace into an observatory, which was furnished with the finest instruments that could be procured. In a few years he made a great number of valuable observations, which he intended to publish, but in March 1789, the observatory having caught fire, the instruments were broken, and the papers burnt, a serious loss to astronomy, particularly as this was the most southern observatory of Europe, in latitude 36°.

At *Palermo* an observatory was constructed in the palace of the viceroy, under the direction of father Piazzi, who went to Paris in 1787 to study astronomy, and who afterwards visited England, in order to consult the principal artists on the construction of instruments. In 1789 he returned to Palermo, and added to the apparatus a fine transit instrument, and a complete circle, made by Ramsden. His first labours were directed to the formation of a correct catalogue of stars, and, as a foundation, he chose Wollaston's catalogue, and particularly, as his chief points of reference, Dr. Maskelyne's 36 stars. The positions of some of the larger stars he verified by nearly a hundred observations, and in the prosecution of this task, in 1801, he discovered a new planet, which he named Ceres, in honour of Sicily, as that island was, on account of its fertility, anciently consecrated to the goddess Ceres. This discovery was the more important, as it excited the curiosity and research of other astronomers, by which three more planets have been since discovered.

English Observatories.

The *Greenwich Observatory*, or the Royal Observatory of England, was built and endowed by King Charles II, who, to use the words of Bailly, "well knew how essential astronomy was to a maritime and commercial people like the English, who aspired to the empire of the seas." This building was erected on the site of the ancient moated tower of Duke Humphrey, uncle to Henry 6, and the first stone of it was laid Aug. 10, 1675, by Mr. Flamsteed, who had been appointed astronomer-royal. It is situated on the highest eminence of Greenwich park, about 160 feet above low-water mark. The soil here is particularly favourable for such an institution, being of a flinty gravel, through which the rain soon passes, and thus the atmosphere is generally dry, which contributes to the preservation of the instruments, as well as to the uniformity of refraction.

This establishment comprehends two principal buildings, one of which is the observatory, and the other the dwelling-house of the astronomer-royal. The observatory is an oblong edifice, running east and west, and containing four rooms or apartments on the ground-floor. The first, or most easterly room, has been lately erected for the reception and fitting up of a very fine transit circle, by Troughton, and a clock of great value by Hardy.

The next apartment is the transit room. It has a double sloping roof, with sliding shutters, which are opened both north and south, with great ease, by pulleys. The transit instrument, which is 8 feet long, and the axis 3 feet, is suspended on two stone pillars. This instrument is famous as having been used by Halley, Bradley, and Maskelyne. It was originally made by Bird, and has been successively improved by Dollond and Troughton. The astronomical or transit clock, which is attached to a stone pillar, was made by Graham, and has been rendered very accurate by Earnshaw.

The third apartment is the assistant observer's library and place for calculation; and the western apartment of the building is the quadrant room. Here is erected a stone pier, running north and south, to which are attached two mural quadrants, each of 8 feet radius. That on the eastern face, which observes the southern meridian, was made by Bird, and the other, which observes the northern, by Graham. Suspended to the western wall is the famous zenith sector, with which Bradley made the observations at Kew and Wanstead, that led to the discoveries of the aberration of light, and the nutation of the earth's axis.

South of the quadrant room is a small wooden building for making occasional observations in any direction, where only the use of a telescope, and an accurate knowledge of the time, are required. It is furnished with sliding shutters on the roof and sides, to view any point of the hemisphere, from the prime vertical down to the southern horizon. It contains some excellent telescopes, particularly a forty-inch achromatic, with a triple object-glass, and a five-feet achromatic, both by Dollond; with a six-feet reflector, by Dr. Herschel.

To the north of the observatory and east of the house are two small buildings, covered with hemispherical sliding domes, in each of which is an equatorial sector, by Sisson, and a clock, by Arnold. These are chiefly used for observing comets.

Of the dwelling-house, the lower apartments are occupied by the astronomer-royal, and over them is a large octagonal room, which contains a great variety of astronomical instruments, with a library, consisting chiefly of scientific and scarce works. On the top of the house is an excellent camera obscura, which could not be better placed for the exhibition of interesting objects.

In Flamsteed's time a well was sunk in the south-east corner of what is now the garden, behind the observatory, for the purpose of seeing the stars in the day-time, and observing the earth's annual parallax. It was a hundred feet deep, with stone stairs down to the bottom: but it has been long arched over, as the improvements in the telescope have rendered it unnecessary for astronomical purposes.

The observations made at the Royal Observatory are universally allowed to possess an unrivalled degree of accuracy. M. Delambre, in a paper composed by him on the life and labours of Dr. Maskelyne, and read before the National Institute, Jan. 4, 1813, makes the following remark. "He (Dr. Maskelyne) has given a catalogue of stars, not numerous, but so accurate, as to have served, almost solely for the last 30 years, as the foundation of all astronomical researches. In short, it may be said of the four volumes of Observations which he has published, that if, by a great revolution, the sciences should be lost, and that this collection only were saved, there would be found in it sufficient materials to construct almost an entire edifice of modern astronomy; which cannot be said of any other collection."

The following are the names of the astronomers who have officiated here in succession, with the times of their services respectively: Flamsteed, 43 years; Halley, 23 years; Bradley, 20 years; Bliss, 2 years; and Maskelyne, 46 years. Maskelyne has been succeeded by John Pond, Esq. F.R.S. who was appointed astronomer-royal in February 1812.

Dr. Herschel's Observatory at Slough, near Windsor, though not a fixed one, will ever claim a distinguished place in the history of astronomical institutions. It differs from all other observatories in plan and apparatus; and it exceeds all others in the number of its discoveries.

In describing this observatory, it should be premised, that Dr. Herschel's labours derive a peculiar character and interest from the circumstance, that his discoveries are the result of his own inventions. For to his profound knowledge of astronomy he unites that of optics, both in theory and practice, by which he has been enabled to cast and polish mirrors for reflecting telescopes, greatly superior to any others, not only in magnifying power, but in collecting, or, as it were, preserving light, by which vision is wonderfully extended, and which he very expressively denominates "the power of penetrating into space." The telescopes, which are all made under his direction, are of various sizes, from two feet in length up to forty feet, and the apparatus and machinery with which they are mounted are also of his invention, and exhibit a very ingenious display of mechanism.

As his larger telescopes could not be conveniently managed within the cover of a building, they are mounted in the open air, where they stand pointing to the heavens in different directions, and make a most magnificent and impressive appearance. Thus they are placed in what has been called the primitive observatory of man, "non sub tecto sed sub cœlo in puro dio."

His largest telescope is 40 feet long and 5 in diameter. It contains a mirror of about a ton weight; and this great instrument, with nearly an additional ton of cases, &c, is managed by a very slight force. It is placed on a large circular frame, which turns on rollers, and the top is suspended by ropes from very lofty ladder-work. Thus, by a system of wheels, pinions, racks, and pulleys, the motions, both horizontal and vertical, are given, and hence any celestial object is readily found and commodiously viewed. It was finished in 1787, and on the first trial a new satellite of Saturn was discovered by it, and a second soon after. A very full and accurate account of his inventions and discoveries, as well as a particular description of his telescopes and their apparatus (with plates), will be found in the Philosophical Transactions, to which he has been a most importa͏nt contributor, having supplied that work with nearly 70 elaborate and ingenious communications.

Two of his telescopes, of smaller size, are famous in the annals of discovery. The first is a two-feet Newtonian reflector, with which his sister Miss Carolina Herschel, whose astronomical attainments do great honour to her sex, discovered six comets; and the other is his seven-feet reflector, by which he discovered the Georgian planet at Bath, in 1781. This telescope has, in consequence of the discovery, been made a constellation in the heavens with the universal approbation of astronomers. It is placed between Gemini, the Lynx, and Auriga, and contains 81 stars. In Bode's atlas it is engraved with its apparatus, and marked Telescopium Herschelii. Dr. Herschel, though in his 76th year, is still an active and indefatigable observer. He was born at Hanover, Nov. 15, 1738, a period which will be ever memorable in the history of astronomy.

The King's private Observatory in Richmond gardens is extremely beautiful in structure and apparatus, as well as in situation. It was built, in 1768, by order of his present majesty George 3, who, it is said, made several observations here, particularly of the transit of Venus in 1769. It contains a fine transit instrument, a zenith sector, and a mural arc, with several good telescopes, especially a ten-feet reflector of Dr. Herschel's. Here is a superb equatorial on the top of the building, which is covered with a moveable roof. There are also two fine orreries, with an excellent collection of philosophical instruments, and some cases of minerals and other natural curiosities. It was built under the direction of Dr. Demainbray, and has been, for some years, in the care of Mr. Rigaud.

Oxford Observatory is a most magnificent structure, and the instruments perfectly correspond with the building. It was begun in 1772, from very ample funds bequeathed by Dr. Radcliffe, and the land on which it stands was the gift of the duke of Marlborough. The transit instrument, which is 10 feet long, shows very small stars in the day-time. It is said to have cost 150 guineas, the zenith sector 200 guineas, and the two mural quadrants 600 guineas. There are also very excellent telescopes and clocks here, the former by Herschel and Dollond, and the latter by Shelton. It was built under the direction of Dr. Hornsby, professor of astronomy in the university, who observed here for many years, and he has been succeeded by Dr. Robertson, the present worthy professor of astronomy. The observations are all registered, and consist chiefly of the right ascensions and zenith distances of the sun, moon, planets, and fixed stars. In Dr. Hornsby's time, the registry was sometimes broken from ill health; for he had no assistant observer; but one has been of late added to the establishment, so that the observations will not, in future, be liable to the like interruptions.

At *Cambridge* there have been small observatories at Christchurch, Trinity, St. John's, &c, and a plan is said to be now on foot for erecting one upon a great scale, and worthy the scientific fame of that learned university.

Portsmouth Observatory.—At the Royal Marine Academy, Portsmouth, there is an observatory under the direction of Mr. Professor Inman, which is of peculiar utility, both in teaching the pupils practical astronomy, and in finding the rate of time-keepers for seamen.

At *Christ's Hospital*, Mr. Wales (who had served under Dr. Maskelyne and Capt. Cook) erected a small observatory at his own expense, when he became master of the royal mathematical school there.

The Royal Society have at Somerset House a small observatory, which is generally superintended by the secretary for the time being.

At *Highbury House*, near Islington, an observatory was built in the year 1787, by Alexander Aubert, Esq, which, for perfection of plan and splendour of apparatus, perhaps has never been equalled by any private individual. This gentleman, whose scientific and liberal pursuits deserve honourable mention, died in the year 1806, and his grand collection of instruments was disposed of by auction, and of course dispersed. Similar notice may be taken of other observatories contemporary with that of Highbury, particularly those of Count Bruhl at Harefield, Sir George Shuckburgh at Shuckburgh, William Larkins, Esq. at Blackheath, and the Hon. Charles Greville at Milford, all of which were on a great scale, and have been discontinued after the demise of the owners. Thus in private observatories, though the astronomers may bequeath their apparatus to their heirs, they cannot transfer either their taste or their science. It is only in public establishments that permanence can be expected.

Among the private observatories of the present day, the following alphabetical list may be also mentioned.

Blackheath -	Stephen Groombridge, Esq.
Blenheim -	Duke of Marlborough.
Cambridge -	Rev. Mr. Catton.
Chiselhurst -	Rev. Francis Wollaston.
Derby -	William Strutt, Esq.
East Sheen -	Rev. William Pearson.
Finsbury Square	Dr. Kelly.

Woolwich -	Royal Mil. Acad.

Scotch Observatories.—In the different universities of Scotland professorships of astronomy have been established, but it has been here, as in most other universities, the theory of the science has been more attended to than the practice. At Edinburgh and Aberdeen there have been, however, observatories; and at Glasgow there is also a small one belonging to the college, but of late a magnificent one has been erected by a society of gentlemen, which is likely, when finished, to be very useful as well as honourable to that commercial city.

Irish Observatories.—In Ireland two observatories have been established on a great scale, the one at Dublin, and the other at Armagh. The observatory belonging to Trinity-college, Dublin, commonly called the Dublin observatory, was begun in the year 1783. It was founded by Dr. Francis Andrews, provost of that college, who bequeathed a large income for this purpose. The apparatus are, a transit instrument of 6 feet focal length, with a 4-

feet axis, bearing 4 inches and a quarter aperture, with three different magnifying powers up to 600. An entire circle of 10 feet diameter on a horizontal axis for measuring meridian altitudes. An equatorial instrument, with circles of 5 feet in diameter: and an achromatic telescope, mounted on a polar axis, and carried by an heliostatic movement. Clocks were also ordered from Mr. Arnold, without any limitation of price.

The situation chosen for the observatory is on elevated ground, about four English miles N. W. of Dublin. The foundation is a solid rock of limestone, of several miles extent; and the soil is very favourable, being a calcareous substance called limestone gravel, which is remarkable for absorbing the rain, and thus contributing to a dry atmosphere. The plan of the building unites at once both elegance and convenience. In the centre is a magnificent dome of three stories high, with a moveable roof for the equatorial instrument, which is placed on a pillar of 16 feet square, of the most substantial masonry, and surrounded by a circular wall at a foot distance, that supports the moveable dome, and also the floors, which in no part touch the pillar: thus, no motion of the floor or wall can be communicated to the instrument. The aperture for observation in the dome is two feet and a half wide.

The most important erection belonging to this establishment is behind the main building, and at right angles to it, in order to obtain an uninterrupted view both north and south. This is the meridian or transit room, which contains both the transit instrument and the circle. It is 37 feet long, by 23 broad, and 21 high. Fine pillars of Portland stone are erected for both instruments on the most firm basis, and the floor is so framed as to let all the pillars rise totally detached from it. The clocks are attached to pillars of the greatest steadiness also: they were made by Arnold, who exerted his best skill, and are finished in a masterly manner; the pallets are of ruby; and all the last holes of the movement jewelled; the suspension springs are of gold, with Arnold's own five-barred pendulum, and cheeks capable of experimental adjustment, so as to make all vibrations isochronal, whatever may be the excursion of the pendulum.

The Rev. Dr. Usher, the first astronomy professor, did not long enjoy the pleasures of astronomy. He died in 1790, before the instruments had been all supplied. He was succeeded by the Rev. Dr. Brinkley, who was reared under Dr. Maskelyne, and had distinguished himself at Cambridge by profound analytical investigations, and who has since greatly enriched the Transactions of the Royal Irish Academy by mathematical and astronomical communications.

From a new 8 feet circle, by Berge, important results are expected, particularly on parallax, aberration of light, and refraction. Dr. B. has been for some time engaged in a series of observations with a view to explain the cause of variations which he has found in the zenith distances of certain stars at different times, which do not seem explicable by any cause at present generally allowed. He has found a difference between the zenith distances of α Lyræ, when in opposition and conjunction, which may be explained by a parallax of about 2 seconds. The new transit circle just erected at Greenwich possesses advantages for such purposes, and great hopes may therefore be formed from the concurrent operations of those two instruments.

Armagh Observatory.—At Armagh, the metropolitan city of Ireland, and anciently the seat of a large university, an observatory has been erected and endowed in 1793, by the most reverend Richard lord Rokeby, then primate of Ireland. It is erected on the summit of a gently rising hill, about 90 feet above the general level of the town. The tower, which joins the dwelling-house, contains a very fine equatorial by Troughton, fixed on a large pillar, which is raised so high that the instrument in the dome can overlook all the buildings. To the east of the house is a range of buildings for the transit room, and other astronomical purposes. The principal instruments, besides the equatorial and transit, are a ten-feet sextant by Troughton; a ten-feet reflecting telescope by Dr. Herschel; a five-feet triple object-glass achromatic telescope by Dollond; and also a fine night glass on an equatorial stand. The clocks are by Earnshaw of London, and Crossthwaite of Dublin.

In this establishment a liberal income is allowed to the principal astronomer, and a good salary to his assistant. It has been superintended from the beginning by the Rev. James Archibald Hamilton, D. D. dean of the cathedral church of St. Coleman, Cloyne. The registered observations here, are those made with the transit instrument and equatorial; and also an account of the temperature and weight of the atmosphere. Of these, a series of about 18 years is preserved. The right ascensions of the sun and moon, compared with the fixed stars, are regular and unbroken; but their north polar distances have not been so constantly taken, as they are only observed by the principal astronomer, whose pastoral duties must occasionally interfere with his astronomical labours.

A TABLE *of the Longitudes and Latitudes of the principal Observatories of Europe, as deduced from the most recent and accurate Determinations.*

OBSERVATORY *Portable*. See EQUATORIAL.

OBTUSE *Angle*, one that is greater than a right-angle.

OBTUSE-*angled Triangle*, is a triangle that has one of its angles obtuse; and it can have only one such.

OBTUSE *Cone*, or OBTUSE-*Angled Cone*, one whose angle at the vertex, by a section through the axis, is obtuse.

OBTUSE *Hyperbola*, one whose asymptotes form an obtuse angle.

OBTUSE-*angular Section of a Cone*, a name given to the hyperbola by the ancient geometricians, because they considered this section only in the obtuse cone.

OCCIDENT, or OCCIDENTAL, west, or westward, in Astronomy; a planet is said to be occident, when it sets after the sun.

OCCIDENT, in Geography, the westward quarter of the horizon, or that part of the horizon where the ecliptic, or the sun's place in it, descends into the lower hemisphere.

OCCIDENT *Equinoctial*, that point of the horizon where the sun sets, when he crosses the equinoctial, or enters the sign Aries or Libra.

OCCIDENT *Estival*, that point of the horizon where the sun sets at his entrance into the sign Cancer, or in our summer when the days are longest.

OCCIDENT *Hybernal*, that point of the horizon where the sun sets at midwinter, when entering the sign Capricorn.

OCCIDENTAL *Horizon*. See HORIZON.

OCCULT, in Geometry, is used for a line that is scarce perceivable, drawn with the point of the compasses, or a black-lead pencil. Occult or dry lines are used in several operations; as the raising of plans, designs of building, pieces of perspective, &c. They are to be effaced or rubbed out when the work is finished.

OCCULTATION, the obscuration of any star or planet, by the interposition of the body of the moon, or any other planet.—The occultation of a star by the moon, if observed in a place whose latitude and longitude are well determined, may be applied to the correction of the lunar tables; but if observed in a place whose latitude only is well known, it may be applied to the determining the longitude of the place.

Circle of Perpetual OCCULTATION. See CIRCLE.

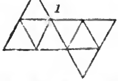
OCEAN, the vast collection of salt water, which encompasses most parts of the earth. By computation it appears that the ocean takes up considerably more of what we know of the terrestrial globe, than the dry land does. This is perhaps easiest known, by taking a good map of the world, and with a pair of scissars clipping out all the water from the land, and weighing the two parts separately: by which means it has been found, that the water occupies about two-thirds of the whole surface of the globe.

The great and universal ocean is sometimes, by geographers, divided into three parts. As, 1st, the Atlantic and European ocean, lying between part of Europe, Africa, and America; 2d, the Indian ocean, lying between Africa, the East-Indian islands, and New Holland; 3d, the Pacific ocean, or great south sea, which lies between the Philippine islands, China, Japan, and New Holland on the west, and the coast of America on the east. The ocean also takes divers other names, according to the different countries it borders on: as the British ocean, German ocean, &c. Also according to the position on the globe; as the northern, southern, eastern, and western oceans.

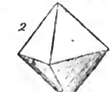
The ocean, penetrating the land at several straits, loses its name of ocean, and assumes that of sea or gulph; as the Mediterranean sea, the Persian gulph, &c. In very narrow places, it is called a strait, &c.

OCTAEDRON, or OCTAHEDRON, one of the five regular bodies; contained under 8 equal and equilateral triangles.—It may be conceived as consisting of two quadrilateral pyramids joined together at their bases.

To form an Octaedron. Join together 8 equal and equilateral triangles, as in fig. 1; then cut the lines half through,



1



2

and fold the figure up by these cut lines, till the extreme edges meet, and form the octaedron, as in figure 2.—In an octaedron, if

A be the linear edge or side,
B its whole surface,
C its solidity, or solid content,
R the radius of the circumscribed sphere, and
r the radius of the inscribed sphere: Then

$A = r\sqrt{6} = R\sqrt{2} = \frac{1}{6}B\sqrt{3} = \sqrt[3]{\frac{3}{2}}C\sqrt{2}$.
$B = 12r^2\sqrt{3} = 4R^2\sqrt{3} = 2A^2\sqrt{3} = 6\sqrt[3]{\frac{3}{4}}C\sqrt[3]{3}$.
$C = 4r^3\sqrt{3} = \frac{4}{3}R^3 = \frac{1}{3}A^3\sqrt{2} = \frac{1}{18}B\sqrt{(B\sqrt{3})}$.
$R = r\sqrt{3} = \frac{1}{2}A\sqrt{2} = \frac{1}{2}\sqrt{B}\sqrt{\frac{1}{3}} = \sqrt[3]{\frac{3}{4}}C$.
$r = \frac{1}{3}R\sqrt{3} = \frac{1}{6}A\sqrt{6} = \frac{1}{6}\sqrt{(B\sqrt{3})} = \frac{1}{2}\sqrt[3]{C}\sqrt{\frac{4}{3}}$.

See my Mensuration, pa. 188, 4th edition.

OCTAGON, is a figure of 8 sides and angles; which, when these are all equal, is also called a regular one, or may be inscribed in a circle.

If the side of a regular octagon be s; then
Its area $= 2s^2 \times (1 + \sqrt{2}) = 4{\cdot}8284271s^2$; and the radius of its circumsc. circle $= \frac{s}{\sqrt{(2 - \sqrt{2})}}$.

OCTAGON, in Fortification, denotes a place that has 8 sides, or 8 bastions.

OCTANT, the 8th part of a circle.

OCTANT, or OCTILE, means also an aspect, or position of two planets, when their places are distant by the 8th part of a circle, or 45 degrees.

OCTAVE, or 8th, in Music, is an interval of 8 sounds; every 8th note in the scale of the gamut being the same, as far as the compass of music requires.

Tones, or sounds, that are octaves to each other, or at an octave's distance, are alike, or the same nearly as the unison. In this case, the more acute of the two makes exactly two vibrations, while the deeper or graver makes but one; whence, they coincide at every two vibrations of the acuter, which, being more frequent, makes this concord more perfect than any other, and as it were an unison. Hence also, it happens, that two chords or strings, of the same matter, thickness, and tension, but the one double the length of the other, produce the octave.

The octave containing in it all the other simple concords, and the degrees being the differences of these concords; it is evident, that the division of the octave comprehends the division of all the rest. By joining therefore all the simple concords to a common fundamental, we have the following series

1	$\frac{5}{6}$	$\frac{4}{5}$	$\frac{3}{4}$	$\frac{2}{3}$	$\frac{5}{8}$	$\frac{3}{5}$	$\frac{1}{2}$
Fund.	3d *l*,	3d *g*,	4th,	5th,	6th *l*,	6th *g*,	8ve.

Mr. Malcolm observes, that any wind instrument being over-blown, the sound will rise to an octave, and no other concord; which he ascribes to the perfection of the octave, and its being next to unison.

Descartes, from an observation of the like kind, viz, that the sound of a whistle, or organ pipe, will rise to an octave, if forcibly blown, concludes, that no sound is heard, but its acute octave seems some way to echo or resound in the ear.

OCTILE. See OCTANT.

OCTOBER, the 8th month of the year, in Romulus's calendar; but the tenth in that of Numa, Julius Cæsar, &c, after the addition of January and February. This month contains 31 days; about the 22d of which, the sun enters the sign Scorpio ♏.

OCTOSTYLE, in Architecture, the face of a building adorned with 8 columns.

ODD *Number*, in Arithmetic, is any number in the series 1, 3, 5, 7, &c. An odd number, when divided by 2, always leaves the remainder 1; and hence all odd numbers are said to be of the form $2n + 1$, and all odd square numbers of the form $8n + 1$, that is, any odd square number, being divided by 8, always leaves the remainder 1: thus $9 = 8 + 1$, $25 = 3 \cdot 8 + 1$, $49 = 6 \cdot 8 + 1$, &c.

The difference of all the consecutive square numbers, beginning with unity, forms the series of odd numbers, 1, 3, 5, 7, 9, &c, as appears by subtracting each preceding square from the following one, in the series of squares.

Squares	1	4	9	16	25	36	49	&c.
Differences	1,	3,	5,	7,	9,	11,	13,	&c.

An odd number cannot be divided by an even number.

Every prime number except 2 is an odd number.

Any power of an odd number is an odd number.

If an odd number divide an even number, it will also divide half that even number.

Every odd number prime to 10, is a divisor of any repetend digit. See NUMBER.

ODDLY-ODD. A number is said to be oddly-odd, when an odd number measures it by an odd number. So 15 is a number oddly-odd, because the odd number 3 measures it by the odd number 5.

OFFING, or OFFIN, in Navigation, that part of the sea which is at a considerable distance from shore; where there is deep water, and no need of a pilot to conduct the ship into port.

OFFSETS, in Surveying, are the perpendiculars let fall, and measured from the station lines, to the corners or bends in the hedge, fence, or boundary of any ground.

OFFSET-*Staff*, a slender rod or staff, of 10 links, or other convenient length. Its use is for measuring the offsetts, and other short lines and distances.

OFFWARD, in Navigation, the same with From the shore, &c.

OGEE, or OG, an ornamental moulding in the shape of an S; consisting of two members, the one concave, and the other convex.

OLBERS, is a name given by some astronomers to a new planet discovered by Dr. Olbers at Bremen, on the 28th of March 1802. It is thus named in honour of this indefatigable astronomer, who has since, viz, on the 29th of March 1807, discovered a second new planet, to which he has given the name of Vesta; the first having also received the appellation of Pallas. The former of these might be otherwise named $Olbers^1$, and the latter $Olbers^2$. The elements of each may be found under their respective names. See PALLAS and VESTA.

OLDENBURG (HENRY), who wrote his name sometimes GRUBENDOL, transposing the letters, was a learned German gentleman, and born in the duchy of Bremen in the Lower Saxony, about the year 1626, being descended from the counts of Aldenburg in Westphalia; whence his name. During the long English parliament in the time of Charles the 1st, he came to England as consul for his countrymen; in which capacity he remained at London in Cromwell's administration. But being discharged of that employment, he was engaged as tutor to lord Henry Obryan, an Irish nobleman, whom he attended to the university of Oxford; and in 1656 he entered himself a student in that university, chiefly to have the benefit of consulting the Bodleian library. He was afterwards appointed tutor to lord William Cavendish, and became intimately acquainted with Milton the poet. During his residence at Oxford, he became also acquainted with the members of that society there, which gave birth to the Royal Society; and on the establishing of this latter, he was elected a member of it: and when the Society found it necessary to have two secretaries, he was chosen assistant to Dr. Wilkins. He applied himself with extraordinary diligence to the duties of this office, and began the publication of the Philosophical Transactions with No. 1, in 1664. In order to discharge this task with more credit to himself and the Society, he held a correspondence with more than seventy learned persons, and others, on a great variety of subjects, in different parts of the world. This fatigue would have been insupportable, had he not, as he told Dr. Lister, managed it so as to make one letter answer another; and that, to be always fresh, he never read a letter before he was ready immediately to answer it: so that the multitude of his letters did not embarrass him, nor ever lie upon his hands. Among others, he was a constant correspondent of Mr. Robert Boyle, and he translated many of that ingenious gentleman's works into Latin.

About the year 1674 he was drawn into a dispute with Mr. Hooke, who complained, that the secretary had not done him justice, in the History of the Transactions, with respect to the invention of the spiral spring for pocket watches; the contest was carried on with some warmth on both sides, but was at length terminated to the honour of Mr. Oldenburg; for, pursuant to an open representation of the affair to the Royal Society, the council thought fit to declare, in behalf of their secretary, that they knew nothing of Mr. Hooke having printed a book entitled Lampas, &c; but that the publisher of the Transactions had conducted himself faithfully and honestly in managing the intelligence of the Royal Society, and that he had given no just cause for such reflections.

Mr. Oldenburg continued to publish the Transactions as before, to No. 136, June 25, 1677; after which the publication was discontinued till the January following; when they were again resumed by his successor in the secretary's office, Mr. Nehemiah Grew, who carried them on till the end of February 1678. Mr. Oldenburg died at his house at Charlton, between Greenwich and Woolwich, in Kent, August 1677, and was interred there, being near 52 years of age.

He published, besides what has been already mentioned, 20 tracts, chiefly on theological and political subjects; in which he principally aimed at reconciling differences, and promoting peace and unanimity.

OLYMPIAD, in Chronology, a revolution or period of 4 years, by which the Greeks reckoned their time: so called from the olympic games, which were celebrated every 4th year, during 5 days, near the summer solstice, on the banks of the river Alpheus, near Olympia, a town of Elis. As each olympiad consisted of 4 years, these were called the 1st, 2d, 3d, and 4th year of each olympiad; the first year commencing with the nearest new moon to the summer solstice.

The first olympiad began the 3938th year of the Julian period, the 3208th of the creation, 776 years before the birth of Christ, or 24 years before the foundation of Rome. And the computation by these ended with the 404th olympiad, being the 440th year of the present vulgar Christian era.

OMBROMETER, a name given by Mr. Roger Pickering (Philos. Trans. No. 473,) to what is more commonly, though less properly, called a pluviameter or rain-gage. See PLUVIAMETER.

OMPHALOPTER, or OMPHALOPTIC, in Optics, a glass that is convex on both sides, popularly called a convex lens.

OPACITY, a quality of bodies which renders them opake, or the contrary of transparency.

The Cartesians make opacity to consist in this, that the pores of the body are not all straight, or directly before each other; or rather not pervious every way. This doctrine however is deficient: for though, to have a body transparent, its pores must be straight, or rather open every way; yet it is inconceivable how it should happen, that not only glass and diamonds, but even water, whose parts are so very moveable, should have all their pores open and pervious every way; while the finest paper, or the thinnest gold leaf, should exclude the light, for want of such pores. So that another cause of opacity must be sought for.

Now all bodies have vastly more pores or vacuities than are necessary for an infinite number of rays to pass freely through them in right lines, without striking on any of the parts themselves. For since water is 19 times lighter or rarer than gold; and yet gold itself is so very rare, that magnetic effluvia pass freely through it, without any opposition; and quicksilver is readily received within its pores, and even water itself by compression; it must have much more pores than solid parts: consequently water must have at least 40 times as much vacuity as solidity.

The cause therefore, why some bodies are opake, does not consist in the want of rectilinear pores, pervious every way; but either in the unequal density of the parts, or in the magnitude of the pores; and to their being either empty, or filled with a different matter; by means of which, the rays of light, in their passage, are arrested by innumerable refractions and reflections, till at length falling on some solid part, they become quite extinct, and are utterly absorbed.

Hence cork, paper, wood, &c, are opake; while glass, diamonds, &c, are pellucid. For in the confines or joining of parts alike in density, such as those of glass, water, diamonds, &c, among themselves, no refraction or reflection takes place, because of the equal attraction every way; so that such of the rays of light as enter the first surface, pass straight through the body, excepting those that are lost and absorbed, by striking on solid parts: but in the bordering of parts of unequal density, such as those of wood and water, both with regard to themselves, and with regard to the air or empty space in their larger pores, the attraction being unequal, the reflections and refractions will be very great; and thus the rays will not be able to pass through such bodies, being continually driven about, till they become extinct.

That this interruption or discontinuity of parts is the chief cause of opacity, Sir Isaac Newton argues, appears from hence; that all opake bodies immediately begin to be transparent, when their pores become filled with a substance of nearly equal density with their parts. Thus, paper dipped in water or oil, some stones steeped in water, linen cloth dipped in oil or vinegar, &c, become more transparent than before.

OPAKE, not translucent, nor transparent, or not admitting a free passage to the rays of light.

OPEN *Flank*, in Fortification, is that part of the flank which is covered by the orillon or shoulder.

OPENING *of the Trenches*, is the first breaking of ground by the besiegers, in order to carry on their approaches towards a place.

OPERA-*Glass*, in Optics, is so called from its use in play-houses, and sometimes a Diagonal Perspective, from its construction, which is as follows. ABCD (fig. 5, pl. 21) represents a tube about 4 inches long; in each side of which there is a hole EF and GH, exactly against the middle of a plane mirror IK, which reflects the rays falling upon it to the convex glass LM; through which they are refracted to the concave eye-glass NO, whence they emerge parallel to the eye at the hole *rs*, in the end of the tube. Let PaQ be an object to be viewed, from which proceed the rays P*c*, *ab*, and Q*d*: these rays, being reflected by the plane mirror IK, will show the object in the direction *cp*, *ba*, *dq*, in the image *pq*, equal to the object PQ, and as far behind the mirror as the object is before it: the mirror being placed so as to make an angle of 45 degrees with the sides of the tube. And as, in viewing near objects, it is not necessary to magnify them, the focal distances of both the glasses may be nearly equal; or if that of LM be 3 inches, and that of NO one inch, the distance between them will be but 2 inches, and the object will be magnified 3 times, being sufficient for the purposes to which this glass is applied.

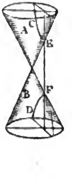
When the object is very near, as XY, it is viewed through a hole *xy*, at the other end of the tube AB, without an eye-glass; the upper part of the mirror being polished for that purpose, as well as the under. The tube unscrews near the object-glass LM, for taking out and cleansing the glasses and mirror. The position of the object will be erect through the concave eye-glass.

The peculiar artifice of this glass is to view a person at a small distance, so that no one shall know who is observed; for the instrument points to a different object from that which is viewed; and as there is a hole on each side, it is impossible to know on which hand the object is situated, which you are viewing.

OPHIUCUS, a constellation of the northern hemisphere; called also Serpentarius.

OPPOSITE *Angles*, or Vertical Angles, are those opposite to each other, made by two intersecting lines; as *a* and *b*, or *c* and *d*. —The opposite angles are equal to each other.

OPPOSITE *Cones*, denote two similar cones vertically opposite, having the same common vertex and axis, and the same sides produced; as the cones A and B.



OPPOSITE *Sections*, or *Hyperbolas*, are those made by cutting the opposite cones by the same plane; as the hyperbolas C and D.—These are always equal and similar, and have the same transverse axis EF, as also the same conjugate axis.

OPPOSITION, is that aspect or situation of two planets or stars, when they are diametrically opposite to each other; being 180°, or a semi-circle apart; and marked thus ☍. —The moon is in opposition to the sun when she is at the full.

OPTIC, or OPTICAL, something that relates to vision, or the sense of seeing, or the science of optics.

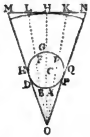
OPTIC *Angle*. See ANGLE.

OPTIC *Axis*. See AXIS.

OPTIC *Chamber*. See CAMERA *Obscura*.

OPTIC *Glasses*, are glasses ground either concave or convex; so as either to collect or disperse the rays of light; by which means vision is improved, and the eye strengthened, preserved, &c.—Among these, the principal are spectacles, reading glasses, telescopes, microscopes, magic lanterns, &c.

OPTIC *Inequality*, in Astronomy, is an apparent irregularity in the motions of very distant bodies; so called, because it is not really in the moving bodies, but arising from the situation of the observer's eye. For if the eye were in the centre, it would always see the motions as they really are.

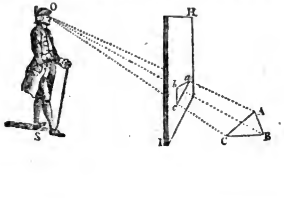


The optic inequality may be thus illustrated. Suppose a body revolving with a real uniform motion, in the periphery of a circle ABD &c; and suppose the eye in the plane of the same circle, but at a distance from it, viewing the motion of the body from O. Now when the body goes from A to B; its apparent motion is measured by the angle AOB or the arch or line HL, which it will appear to describe. But while it moves through the arch BD in an equal time, its apparent motion will be determined by the angle BOD, or the arch or line LM, which is less than the former LH. But it spends the same time in describing DE, as it does in AB or BD; during all which time of describing DE it appears stationary in the point M. When it really describes EFGIQ, it will appear to pass over MLHKN; so that it will seem to have gone retrograde. And lastly, from Q to P it will again appear stationary in the point N.

OPTIC *Nerves*, the second pair of nerves, springing from the crura of the medulla oblongata, and passing thence to the eye. These are covered with two coats, which they take from the dura and pia mater; and which, by their expansions, form the two membranes of the eye, called the uvea and cornea. And the retina, which is a third membrane, and the immediate organ of sight, is only an expansion of the fibrous, or inner, and medullary part of these nerves.

OPTIC *Pencil*. See PENCIL *of Rays*.

OPTIC *Pyramid*, in Perspective, is the pyramid ABCO, whose base is the visible object ABC, and the vertex is in the eye at O; being formed by rays drawn from the



several points of the perimeter to the eye. Hence may appear what is meant by optic triangle.

OPTIC *Place*, of a star, &c, is that point or part of its orbit, which is determined by our sight, when the star is seen there. This is either true or apparent; true when the observer's eye is supposed to be at the centre of the motion; or apparent, when his eye is at the circumference of the earth. See also PLACE.

OPTIC *Rays*, particularly means those by which an optic pyramid, or optic triangle, is terminated. As OA, OB, OC, &c.

OPTICIAN, a person skilled in optics.

OPTICS, the science of vision; including Catoptrics, and Dioptrics; and even Perspective; as also the whole doctrine of light and colours, and all the phenomena of visible objects.

Optics, in its more extensive acceptation, is a mixed mathematical science; which explains the manner in which vision is performed in the eye; treats of sight in general; gives the reasons of the several modifications or alterations, which the rays of light undergo in the eye; and shows why objects appear sometimes greater, sometimes smaller, sometimes more distinct, sometimes more confused, sometimes nearer and sometimes more remote. In this extensive signification it is considered by Newton, in his excellent work on this science. Indeed optics makes a considerable branch of natural philosophy; both as it explains the laws of nature, according to which vision is performed; and as it accounts for a variety of physical phenomena, otherwise inexplicable.

The principal authors and discoveries in Optics, are the following:—Euclid seems to be the earliest author on optics that we have. He composed a treatise on optics and catoptrics; dioptrics being less known to the ancients; though it was not entirely unknown to them, for among the phenomena, at the beginning of that work, Euclid remarks the effect of bringing an object into view, by refraction, in the bottom of a vessel, by pouring water into it, which could not be seen over the edge of the vessel, before the water was poured in; and other authors speak of the then known effects of glass globes &c, both as burning glasses, and as to bodies seen through them. Euclid's work however is chiefly on catoptrics, or reflected rays; in which he shows, in 31 propositions, the chief properties of them, both in plane, convex, and concave surfaces, in his usual geometrical manner; beginning with that concerning the equality of the angles of incidence and reflection, which he demonstrates; and, in the last proposition, showing the effect of a concave speculum, as a burning glass, when exposed to the rays of the sun. The effects of burning glasses, both by refraction and reflection, are noticed by several others of the ancients; and it is probable that the Romans had a method of lighting their sacred fire by some such means. Aristophanes, in one of his comedies, introduces a person as making use of a globe filled with water to cancel a bond that was against him, by thus melting the wax of the seal. And if we give but a small degree of credit to what some ancient historians are said to have written concerning the exploits of Archimedes, we shall be induced to think that he constructed some very powerful burning mirrors. It is said that this eminent geometrician wrote a treatise on the subject of them, though it be not now extant; as also concerning the appearance of a ring or circle under water, and therefore could not have been ignorant of the common phenomena of refraction. We find many questions concerning such optical appearances in Aristotle. This author was also sensible, that it is the reflection of light from the atmosphere which prevents total darkness after the sun sets, and in places where he does not shine in the day-time. He was also of opinion, that rainbows, halos, and mock suns, were all occasioned by the reflection of the sunbeams in different circumstances, by which an imperfect image of his body was produced, the colour only being exhibited, and not his proper figure.

The ancients were not only acquainted with the more ordinary appearances of refraction, but knew also the production of colours by refracted light. Seneca says, that when the light of the sun shines through an angular piece of glass, it shows all the colours of the rainbow. These colours however, he says, are false, such as are seen in a pigeon's neck when it changes its position; and of the same nature he says is a speculum, which, without having any colour of its own, assumes that of any other body. It appears also, that the ancients were not unacquainted with the magnifying power of glass globes filled with water, though it does not appear that they knew any thing of the reason of this power: and it is supposed that the ancient engravers made use of a glass globe filled with water to magnify their figures, that they might work to more advantage.

Ptolemy, about the middle of the second century, wrote a considerable treatise on optics. The work is lost; but from the accounts given of it by others, it appears that he there treated of astronomical refractions. The first astronomers were not aware that the intervals between stars appear less when near the horizon than in the meridian; and on this account they must have been much embarrassed in their observations: but it is evident that Ptolemy was aware of this circumstance by the caution which he gives to allow something for it, whenever recourse is had to ancient observations. This philosopher also advances a very sensible hypothesis to account for the remarkably great apparent size of the sun and moon when seen near the horizon. The mind, he says, judges of the size of objects by means of a preconceived idea of their distance from us: and this distance is fancied to be greater when a number of objects are interposed between the eye and the body we are viewing: which is the case when we see the heavenly bodies near the horizon. In his Almagest, however, he ascribes this appearance to a refraction of the rays by vapours, which actually enlarge the angle under which the luminaries appear; just as the angle is enlarged by which an object is seen from under water.

Alhazen, an Arabian writer, was the next author of any celebrity, and wrote about the year 1100. Alhazen made many experiments on refraction, at the surface between air and water, air and glass, and water and glass; and hence he deduced several properties of atmospherical refraction; such as "that it increases the altitudes of all objects in the heavens;" and he first advanced that the stars are sometimes seen above the horizon by means of refraction, when they are really below it: which observation was confirmed by Vitello, Walther, and especially by the observations of Tycho Brahe. Alhazen observed, that refraction contracts the diameters and distances of the heavenly bodies, and that it is the cause of the twinkling of the stars. This refractive power he ascribed, not to the vapours contained in the air, but to its different degrees of transparency. And it was his opinion, that so far from vapour being the cause of the heavenly bodies appearing larger near the horizon, that it would make them appear less; observing that two stars appear nearer together in the horizon, than near the meridian. This phenomenon he ranks among optical deceptions. We judge of distance, he says, by comparing the angle under which objects appear, with their supposed distance; so that if these angles be nearly equal, and the distance of one object be conceived greater than that of the other, this will be imagined to be larger. And he further observes, that the sky near the horizon is always imagined to be farther from us than any other part of the concave surface.

In the writings of Alhazen, we also find the first distinct account of the magnifying power of glasses; and it is not improbable that his writings on this head gave rise to the useful invention of spectacles: for he says, that if an object be applied close to the base of the larger segment of a sphere of glass, it will appear magnified. He also treats of the appearance of an object through a globe, and says that he was the first who observed the refraction of rays into it.

In 1270, Vitello, a native of Poland, published a treatise on optics, containing all that was valuable in Alhazen, and digested in a better manner. He observes, that light is always lost by refraction, which makes objects appear less luminous. He gave a table of the results of his experiments on the refractive powers of air, water, and glass, corresponding to different angles of incidence. He ascribes the twinkling of the stars to the motion of the air in which the light is refracted; and he illustrates this hypothesis, by observing that they twinkle still more when viewed in water put in motion. He also shows, that refraction is necessary, as well as reflection, to form the rainbow; because the body which the rays fall upon is a transparent substance, at the surface of which one part of the light is always reflected, and another refracted. And he makes some ingenious attempts to explain refraction, or to ascertain the law of it. He also considers the foci of glass spheres, and the apparent size of objects seen through them; though with but little accuracy. To Vitello may be traced the idea of seeing images in the air. He endeavours to show, that it is possible, by means of a cylindrical convex speculum, to see the images of objects in the air, out of the speculum, when the objects themselves cannot be seen.—The Optics of Alhazen and Vitello were published at Basil in 1572, by Fred. Risner.

Contemporary with Vitello, was Roger Bacon, a man of very extensive genius, who wrote upon almost every branch of science; though it is thought his improvements in optics were not carried far beyond those of Alhazen and Vitello. He even assents to the absurd notion, held by all philosophers down to his time, that visible rays proceed from the eye, instead of towards it. From many stories related of him however, it would seem, that he made greater improvements than appear in his writings. It is said he had the use of spectacles; that he had contrivances, by reflection from glasses, to see what was doing at a great distance, as in an enemy's camp. And lord chancellor Bacon relates a story, of his having apparently walked in the air between two steeples, and which he supposed was effected by reflection from glasses, while he walked upon the ground. See the article Bacon.

About 1279 was written a treatise on optics by Peccam, archbishop of Canterbury.

One of the next who distinguished himself as a theoretical optician, was Maurolyc, teacher of mathematics at Messina. In a treatise De Lumine et Umbra, published in 1575, he demonstrates, that the crystalline humour of the eye is a lens that collects the rays of light issuing from the objects, and throws them upon the retina, where the focus of each pencil is situated. From this principle he discovered the reason why some people are short-sighted, and others long-sighted; also why the former are relieved by concave glasses, and the others by convex ones.

Contemporary with Maurolyc, was John Baptista Porta, of Naples. He discovered the camera obscura, which throws considerable light on the nature of vision. His house was the constant resort of all the ingenious persons at Naples, whom he formed into what he called An Academy of Secrets; each member being obliged to contribute something that was not generally known, and might be useful. By this means he was furnished with materials for his Magia Naturalis, which contains his account of the camera obscura, and the first edition of which was published, as he informs us, when he was not quite 15 years old. He also gave the first hint of the magic lantern; which Kircher afterwards followed and improved. His experiments with the camera obscura convinced him, that vision is performed by the intromission of something into the eye, and not by visual rays proceeding from it, as had been formerly imagined; and he was the first who fully satisfied himself and others on this subject. He justly considered the eye as a camera obscura, and the pupil the hole in the window-shutter; but he was mistaken in supposing that the crystalline humour corresponds to the wall which receives the images; nor was it discovered till the year 1604, that this office is performed by the retina. He made a variety of just remarks concerning vision; and particularly explained several cases in which we imagine things to be without the eye, when the appearances are occasioned by some affection of the eye itself, or by some motion within the eye.—He remarked also that, in certain circumstances, vision will be assisted by convex or concave glasses; and he seems even to have made some small advances towards the discovery of telescopes.

Other treatises on optics, with various and gradual improvements, were afterwards successively published by several authors: as Aguilon, Opticorum libr. 6, Antv. 1613: L'Optique, Catoptrique, et Dioptrique of Herigone, in his Cursus Math. Paris 1637: the Dioptrics of Descartes, 1637: L'Optique et Catoptrique of Mersenne, Paris 1651: Scheiner, Optica, Lond. 1652: Manchini, Dioptrica Practica, Bologna, 1660: Barrow, Lectiones Opticæ, London 1663: James Gregory, Optica Promota, Lond. 1663: Grimaldi, Physico-mathesis de Lumine, Coloribus, et Iride, Bononia, 1665: Scaphusa, Cogitationes Physico-mechanicæ de Natura Visionis, Heidel. 1670: Kircher, Ars Magna Lucis et Umbræ, Rome 1671: Cherubin, Dioptrique Oculaire, Paris 1671: Leibnitz, Principe Generale de l'Optique, Leipsic Acts 1682: Newton's Optics and Lectiones Opticæ, 4to and 8vo, 1704 &c: Molyneux, Dioptrics, Lond. 1692: Dr. Jurin's Theory of Distinct and Indistinct Vision.—There is also a large and excellent work on optics, by Dr. Smith, 2 vols 4to; and an elaborate history of the present state of discoveries relating to vision, light, and colours, by Dr. Priestley, 4to, 1772; with a multitude of other authors of inferior note; besides lesser and occasional tracts and papers in the Memoirs of the several learned Academies and Societies of Europe; with improvements by many other persons, among whom are the respectable names of Snell, Fermat, Kepler, Huygens, Hortensius, Boyle, Hooke, Lahire, Lowthorp, Cassini, Halley, Delisle, Euler, Dollond, Clairaut, Dalembert, Zeiher, Bouguer, Buffon, Nollet, Baume; but the particular improvements by each author must be referred to the history of his life, under the articles of their names; while the history and improvements of the several branches are to be found under the various particular articles, as, Light, Colours, Reflection, Refraction, Inflection, Transmission, &c, Spectacles, Telescope, Microscope, &c, &c.

ORB, a spherical shell, hollow sphere, or space contained between two concentric spherical surfaces.—The ancient astronomers conceived the heavens as consisting of several vast azure transparent orbs or spheres, inclosing one another, and including the bodies of the planets.

The ORBIS *Magnus*, or *Great* ORB, is that in which the sun is supposed to revolve; or rather it is that in which the earth makes its annual circuit.

ORBIT, is the path of a planet or comet; being the curve line described by its centre, in its proper motion in the heavens. So the earth's orbit, is the ecliptic, or the curve it describes in its annual revolution about the sun.

The ancient astronomers made the planets describe circular orbits, with a uniform velocity. Copernicus himself could not believe they should do otherwise; being unable to disentangle himself entirely from the excentrics and epicycles to which they had recourse, to account for the inequalities in their motions.

But Kepler found, from observations, that the orbit of the earth, and that of every primary planet, is an ellipsis, having the sun in one of its foci; and that they all move in these ellipses by this law, that a radius drawn from the centre of the sun to the centre of the planet, always describes equal areas in equal times; or, which is the same thing, in unequal times, it describes areas that are proportional to those times. And Newton has since demonstrated, from the nature of universal gravitation and projectile motion, that the orbits must of necessity be ellipses, and the motions are found to observe that law, both of the primary and secondary planets; excepting in so far as their motions and paths are disturbed by their mutual actions on one another; as the orbit of the earth by that of the moon; or that of Saturn by the action of Jupiter; &c.

Of these elliptic orbits, there have been two kinds assigned; the first that of Kepler and Newton, which is the common or conical ellipse; for which Seth Ward, though he himself employs it, thinks we might venture to substitute circular orbits, by using two points, taken at equal distances from the centre, on one of the diameters, as is done in the foci of the ellipsis, and which is called his Circular Hypothesis. The second is that of Cassini, of this nature, viz, that the products of the two lines drawn from the two foci, to any point in the circumference, are everywhere equal to the same constant quantity; whereas, in the common ellipse, it is the sum of those two lines that is always a constant quantity.

The orbits of the planets are not all in the same plane with the ecliptic, which is the earth's orbit round the sun, but are variously inclined to it, and to each other: but still the plane of the ecliptic, or earth's orbit, intersects the plane of the orbit of every other planet, in a right line which passes through the sun, called the line of the nodes, and the points of intersection of the orbits themselves are called the nodes.

The mean semidiameters of the several orbits, or the mean distances of the planets from the sun, with the excentricities of the orbits, their inclination to the ecliptic, and the places of their nodes, are as in the following table; where the 2d column contains the proportions of semidiameters of the orbits, the true semidiameter of that of the earth being 95 millions of miles; and the 3d column shows what part of the semidiameters the excentricities are equal to.

Planets.	Propor. semid. of orbit.	Excentr. in pts. of mean dist.	Inclina. of orbit.	Ascending node.
Mercury - - -	387	$\frac{4}{19}$	6° 54′	♉ 14° 43′
Venus - - - -	723	$\frac{1}{138}$	3 20	♊ 13 59
Earth - - - -	1000	$\frac{1}{60}$	0 0	- - -
Mars - - - -	1524	$\frac{1}{11}$	1 52	♉ 17 17
Vesta - - - -	2355	$\frac{1}{11}$	7 8⅓	♊ 13 18
Juno - - - -	2664	$\frac{1}{4}$	13 4	♍ 21 4
Pallas - - - -	2765	$\frac{1}{4}$	34 38	♍ 22 31
Ceres - - - -	2767	$\frac{1}{13}$	10 38	♊ 21 7
Jupiter - - - -	5201	$\frac{1}{21}$	1 20	♋ 7 29
Saturn - - - -	9539	$\frac{1}{18}$	2 30	♋ 21 13
Uranus - - - -	19034	$\frac{1}{21}$	0 46½	♊ 12 54

The orbits of comets are also very excentric ellipses.

ORDER, in Architecture, a system of the several members, ornaments, and proportions of columns and pilasters, or a regular arrangement of the projecting parts of a building, especially the column, so as to form one beautiful whole.

There are five orders of columns, of which three are Greek, viz, the Doric, Ionic, and Corinthian; and two Italic, viz, the Tuscan and Composite. The three Greek orders represent the three different manners of building, viz, the solid, the delicate, and the middling: the two Italic ones are imperfect productions of these.

ORDER, in Astronomy. A planet is said to move according to the order of the signs, when it is direct; proceeding from Aries to Taurus, thence to Gemini, &c. As, on the contrary, its motion is contrary to the order of the signs, when it is retrograde, or goes backward, from Pisces to Aquarius, &c.

ORDER, in the Geometry of Curve Lines, is denominated from the rank or order of the equation by which the geometrical line is expressed; so, the simple equation, or 1st power, denotes the 1st order of lines, which is the right line; the quadratic equation, or 2d power, defines the 2d order of lines, which are the conic sections and circle; the cubic equation, or 3d power, defines the 3d order of lines; and so on.

Or, the orders of lines are denominated from the number of points in which they may be cut by a right line. Thus, the right line is of the 1st order, because it can be cut only in one point by a right line; the circle and conic sections are of the 2d order, because they can be cut in two points by a right line; while those of the 3d order, are such as can be cut in three points by a right line; and so on.

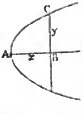
It is to be observed, that the order of curves is always one degree lower than the corresponding line; because the 1st order, or right line, is no curve; and the circle and conic sections, which are the 2d order of lines, are only the 1st order of curves; &c. See CURVES and LINES. Also Newton's Enumeratio Linearum Tertii Ordinis.

ORDINATES, in the Geometry of Curve Lines, are right lines drawn parallel to each other, and cutting the curve in a certain number of points.

The parallel ordinates are usually all cut by some other line, which is called the absciss, and commonly the ordinates are perpendicular to the abscissal line. When this line is a diameter of the curve, the property of the ordinates is then the most remarkable; for, in the curves of the first kind, or the conic sections and circle, the ordinates are all bisected by the diameter, making the part on one side of it equal to the part on the other; and in the curves of the 2d order, which may be cut by an ordinate in three points, then the three parts of the ordinate, lying between these three intersections of the curve and the intersection with the diameter, have the part on one side the diameter equal to both the two parts on the other side of it. And so for curves of any order, whatever the number of intersections may be, the sum of the parts of any ordinate, on one side of the diameter, being in all cases equal to the sum of the parts on the other side of it.

The use of ordinates in a curve, and their abscisses, is to define or express the nature of the curve, by means of the general relation or equation between them; and the greatest number of factors, or the dimensions of the highest term, in such equation, is always the same as the order of the line; that equation being a quadratic, or its highest term of two dimensions, in the lines of the 2d order, being the circle and conic sections; and a cubic equation, or its highest term containing 3 dimensions, in the lines of the 3d order; and so on.

Thus, y denoting an ordinate BC, and x its absciss AB; also a, b, c, &c, given quantities: then $y^2 = ax^2 + bx + c$ is the general equation for the lines of the 2d order; and $xy^2 - cy = ax^3 + bx^2 + cx + d$ is the equation for the lines of the 3d order; and so on.



ORDNANCE, are all sorts of great guns, used in war; such as cannons, mortars, howitzers, &c.

ORFFYREUS's *Wheel*, in Mechanics, is a machine so called from its inventor, which he asserted to be a perpetual motion. This machine, according to the account given of it by Gravesande, in his Œuvres Philosophiques, published by Allemand, Amst. 1774, consisted externally of a large circular wheel, or rather drum, 12 feet in diameter, and 14 inches deep; being very light, as it was formed of an assemblage of deals, having the intervals between them covered with waxed cloth, to conceal the interior parts of it. The two extremities of an iron axis, on which it turned, rested on two supports. On giving a slight impulse to the wheel, in either direction, its motion was gradually accelerated; so that after two or three revolutions it acquired so great a velocity as to make 25 or 26 turns in a minute. This rapid motion it actually preserved during the space of 2 months, in a chamber of the landgrave of Hesse, the door of which was kept locked, and sealed with the landgrave's own seal. At the end of that time it was stopped, to prevent the wear of the materials. The professor, who had been an eye-witness to these circumstances, examined all the external parts of the machine, and was convinced that there could not be any communication between it and any neighbouring room. Orffyreus however was so incensed, or pretended to be so, that he broke the machine in pieces, and wrote on the wall, that it was the impertinent curiosity of professor Gravesande which made him take this step. The prince of Hesse, who had seen the interior parts of this wheel, but sworn to secrecy, being asked by Gravesande, whether, after it had been in motion for some time, there was any change observable in it, and whether it contained any pieces that indicated fraud or deception, answered both questions in the negative, and declared that the machine was of a very simple construction.

ORGANICAL *Description of Curves*, is the description of them on a plane, by means of instruments, and commonly by a continued motion. The most simple construction of this kind, is that of a circle by means of a pair of compasses. The next is that of an ellipse by means of a thread and two pins in the foci, or the ellipse and hyperbola, by means of the elliptical and hyperbolic compasses. A great variety of descriptions of this sort are to be found in Schooten De Organica Conic. Sect. in Plano Descriptione; in Newton's Arithmetica Universalis, De Curvarum Descriptione Organica; Maclaurin's Geometria Organica; Brackenridge's Descriptio Linearum Curvarum; &c.

ORGUES, or ORGANS, in Fortification, long and thick pieces of wood, shod with pointed iron, and hung each by a separate rope over the gate-way of a town, ready on any surprise or attempt of the enemy to be let down to stop up the gate. The ends of the several ropes are wound about a windlass, so as to be let down all together.

ORGUES is also used for a machine composed of several harquebusses or musket-barrels, bound together; so as to make several explosions at the same time. They are used to defend breaches and other places attacked.

ORIENT, the east, or eastern point of the horizon.

ORIENT *Equinoctial*, is used for that point of the horizon where the sun rises when he is in the equinoctial, or when he enters the signs Aries and Libra.

ORIENT *Æstival*, is the point where the sun rises in the middle of summer, when the days are longest.

ORIENT *Hybernal*, is the point where the sun rises in the middle of winter, when the days are shortest.

ORIENTAL, situated towards the east with regard to us: in opposition to occidental or the west.

ORIENTAL *Astronomy, Philosophy*, &c, used for those of the east, or of the Arabians, Chaldeans, Persians, Indians, &c.

ORILLON, in Fortification, a small rounding of earth, lined with a wall, raised on the shoulder of those bastions that have casemates, to cover the cannon in the retired flank, and prevent their being dismounted by the enemy.—There are other sorts of orillons, properly called epaulements, or shoulderings, which are almost of a square figure.

ORION, a constellation of the southern hemisphere, with respect to the ecliptic, but half in the northern, and half on the southern side of the equinoctial, which runs across the middle of his body. The stars in this constellation are, 38 in Ptolemy's catalogue, 42 in Tycho's, 62 in Hevelius's, and 78 in Flamsteed's. But some telescopes have discovered several thousands of stars in this constellation, of which there are 2 of the first magnitude, and 4 of the second, besides a great many of the third and fourth. One of those two stars of the first magnitude is on the middle of the left foot, and is called Regel; the other is on the right shoulder, and called Betelguese; of the 4 of the second magnitude, one is on the left shoulder, and called Bellatrix, and the other three are in the belt, lying nearly in a right line and at equal distances from each other, forming what is popularly called the Yard-wand.

This constellation is one of the 48 old asterisms, and one of the most remarkable in the heavens. It is in the figure of a man, having a sword by his side, and seems attacking the bull with a club in his right hand, his left bearing a shield.

No constellation was so terrible to the mariners of the early periods, as this of Orion. He is mentioned in this way by all the Greek and Latin poets, and even by their historians; his rising and setting being attended by storms and tempests: and as the northern constellations are made the followers of the Pleiades; so are the southern ones made the attendants of Orion.

The name of this constellation is also met with in Scripture several times, viz, in the books of Job, Amos, and Isaiah. In Job it is asked, "Canst thou bind the sweet influence of the Pleiades, or loose the bands of Orion?" And Amos says, "Seek him that maketh the Seven Stars and Orion, and turneth the shadow of death into morning."

ORION'S *River*, the same as the constellation Eridanus.

ORLE, ORLET, or ORLO, in Architecture, a fillet under the ovolo, or quarter-round of a capital.—When it is at the top or bottom of the shaft, it is called the cincture. —Palladio also uses Orlo for the plinth of the bases of columns and pedestals.

ORRERY, an astronomical machine, for exhibiting the various motions and appearances of the sun and planets; hence often called a Planetarium. The term Orrery applied to this instrument, we are informed by Desaguliers, arose from the following circumstance:—Mr. Rowley, a mathematical instrument-maker, having got one from Mr. George Graham, the original inventor, to be sent abroad with some of his own instruments, he copied it, and afterwards constructed one for the earl of Orrery. Sir Richard Steele, who knew nothing of Mr. Graham's machine, thinking to do justice to the first encourager, as well as to the inventor of such a curious instrument, called it an orrery, and gave Rowley the praise due to Mr. Graham. Desaguliers's Experim. Philos. vol. 1, pa. 430. The figure of this grand orrery is exhibited at fig. 1, pl. 24. It is since made in various other figures.

ORTEIL, in Fortification. See BERME.

ORTELIUS (ABRAHAM), a celebrated geographer, was born at Antwerp, in 1527. He was well skilled in the languages and mathematics, and acquired such reputation by his skill in geography, that he was surnamed the Ptolemy of his time. Justus Lipsius, and most of the learned men of the 16th century, were our author's intimate friends. He passed some time at Oxford in the reign of Edward the 6th; and he visited England a second time in 1577.

His Theatrum Orbis Terræ was the completest work of the kind that had ever been published, and gained our author a reputation adequate to his immense labour in compiling it. He wrote also several other excellent geographical works; the principal of which are, his Thesaurus, and his Synonyma Geographica.—The learned world is also indebted to him for the Britannia, which was undertaken by Cambden at his request.—He died at Antwerp, 1598, at 71 years of age.

ORTHODROMICS, in Navigation, is Great-circle sailing, or the art of sailing in the arch of a great circle, which is the shortest course: for the arch of a great circle is orthodromia, or the shortest distance between two points or places.

ORTHOGONIAL, in Geometry, is the same as rectangular, or right-angled.—When the term refers to a plane figure, it supposes one leg or side to stand perpendicular to the other: when spoken of solids, it supposes their axes to be perpendicular to the plane of the horizon.

ORTHOGRAPHIC, or ORTHOGRAPHICAL *Projection of the Sphere*, is the projection of its surface or of the sphere on a plane, passing through the middle of it, by an eye vertically at an infinite distance. See PROJECTION.

ORTHOGRAPHY, in Geometry, is the drawing or delineating the front plan or side of any object, and of expressing the heights or elevations of every part: being so called from its delineating objects by perpendicular right lines falling on the geometrical plan; or rather, because all the horizontal lines are here straight and parallel, and not oblique as in representations of perspective.

ORTHOGRAPHY, in Architecture, is the profile or elevation of a building, showing all the parts in their true proportion. This is either external or internal.

External ORTHOGRAPHY, is a delineation of the outer face or front of a building; showing the principal wall with its apertures, roof, ornaments, and every thing visible to an eye placed before the building. And

Internal ORTHOGRAPHY, called also a Section, is a delineation or draught of a building, such as it would appear if the external wall were removed.

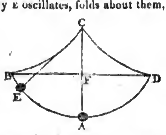
ORTHOGRAPHY, in Fortification, is the profile, or representation of a work; or a draught so conducted, as that the length, breadth, height, and thickness of the several parts are expressed, such as they would appear if it were perpendicularly cut from top to bottom.

ORTHOGRAPHY, in Perspective, is the front side of any place; that is, the side or plane that lies parallel to a straight line that may be imagined to pass through the outward convex points of the eyes, continued to a convenient length.

ORTIVE, or *Eastern Amplitude*, in Astronomy, is an arch of the horizon intercepted between the point where a star rises, and the east point of the horizon.

OSCILLATION, in Mechanics, denotes the vibration, or the reciprocal ascent and descent of a pendulum.

If a simple pendulum be suspended between two semi-cycloids, BC, CD, that have the diameter CF of the generating circle equal to half the length of the string, so that the string, as the body E oscillates, folds about them, then will the body oscillate in another cycloid BEAD, similar and equal to the former. And the time of the oscillation in any arc AE, measured from the lowest point A, is always the same constant quantity, whether that arc be larger or smaller. But the oscillations in a circle are unequal, those in the smaller arcs being less than those in the larger; and so always less and less as the arcs are smaller,



but still greater than the time of oscillation in a cycloidal arc; till the circular arc becomes very small, and then the time of oscillation in it is very nearly equal to the time in the cycloid, because the circle and cycloid have the same curvature at the vertex, the length of the string being the common radius of curvature to them both at that point.

The time of one whole oscillation in the cycloid, or of an ascent and descent in any arch of it, is to the time in which a heavy body would fall freely through CF or FA, the diameter of the generating circle, or through half the length of the pendulum string, as the circumference of a circle is to its diameter, that is as 3·1416 to 1. So that if l denote the length of the pendulum CA, and $g = 16\frac{1}{12}$ feet $= 193$ inches, the space through which a heavy body falls in the 1st second of time, and $p = 3·1416$ the circumference of a circle whose diameter is 1: then by the laws of falling bodies, it is $\sqrt{g} : \sqrt{\frac{1}{2}l} :: 1'' : \sqrt{\frac{l}{2g}}$, the time of falling through CF or $\frac{1}{2}l$; therefore $1 : p :: \sqrt{\frac{l}{2g}} : p\sqrt{\frac{l}{2g}}$, which is the time of one vibration in any arch of the cycloid which has the diameter of its generating circle equal to $\frac{1}{2}l$. Or, by substituting the known numbers for p and g, the time of an oscillation becomes barely $\frac{4}{25}\sqrt{l}$ or $\frac{16}{100}\sqrt{l}$ very nearly, or more nearly $\frac{18}{113}l$, l being the length of the pendulum in inches. And therefore this is also very nearly the time of an oscillation in a small circular arc, whose radius is l inches.

Hence the times of the oscillation of pendulums of different lengths, are directly in the subduplicate ratio of their lengths, or as the square roots of their lengths.—The more exact time of oscillating in a circular arc, when this is of some finite small length, is $\frac{4}{25}\sqrt{l} \times (1 + \frac{h}{8l})$; where h is the height of the vibration, or the versed sine of the single arc of ascent or descent, to the radius l.

The celebrated Huygens first resolved the problem concerning the oscillations of pendulums, in his book De Horologio Oscillatorio, reducing compound pendulums to simple ones. And his doctrine is founded on this hypothesis, that the common centre of gravity of several bodies, connected together, must ascend exactly to the same height from which it fell, whether those bodies be united, or separated from one another in ascending again, provided that each begin to ascend with the velocity acquired by its descent.

This supposition was opposed by several persons, and very much suspected by others. And those even who believed the truth of it, yet thought it too daring to be admitted without proof into a science which demonstrates every thing.

At length James Bernoulli demonstrated it, from the nature of the lever; and published his solution in the Mem. Acad. des Scienc. of Paris, for the year 1703. After his death, which happened in 1705, his brother John Bernoulli gave a more easy and simple solution of the same problem, in the same Memoirs for 1714; and about the same time, Dr. Brook Taylor published a similar solution in his Methodus Incrementorum: which gave occasion to a dispute between these two mathematicians, who accused each other of having stolen their solutions. The particulars of which dispute may be seen in the Leipsic Acts for 1716, and in Bernoulli's works, printed in 1743.

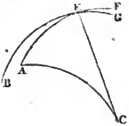
Axis of OSCILLATION, is a line parallel to the horizon, supposed to pass through the centre or fixed point about which the pendulum oscillates, and perpendicular to the plane in which the oscillation is made.

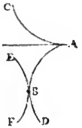
Centre of OSCILLATION, in a suspended body, is a certain point in it, such that the oscillation of the body will be made in the same time as if that point alone were suspended at that distance from the point of suspension. Or it is the point into which, if the whole weight of the body be collected, the several oscillations will be performed in the same time as before: the oscillations being made only by the force of gravity of the oscillating body. See CENTRE *of Oscillation*.

OSCULATION, in Geometry, denotes the contact between any curve and its osculatory circle, that is, the circle of the same curvature with the given curve, at the point of contact or of osculation. If AC be the evolute of the involute curve AEF, and the tangent CE the radius of curvature at the point E, with which, and the centre C, if the circle BEG be described; this circle is said to osculate the curve AEF in the point E, which point E M. Huygens calls the point of osculation, or kissing point.

The line CE is called the osculatory radius, or the radius of curvature; and the circle BEG the osculatory or kissing circle.

The evolute AC is the locus of the centres of all the circles that osculate the involute curve AEF.





OSCULATION also means the point of concourse of two branches of a curve which touch each other. For example, if the equation of a curve be $y = \sqrt{x} + \sqrt[4]{x^5}$, it is easy to see that the curve has two branches touching one another at the point where $x = 0$, because the roots have each the signs + and −.

The point of osculation differs from the cusp or point of retrocession (which is also a kind of point of contact of two branches) in this, that in this latter case the two branches terminate, and pass no farther, but in the former the two branches exist on both sides of the point of osculation. Thus, in the second figure above, the point B is the osculation of the two branches ABD, EBF; but A, though it is also a tangent point, is a cusp or the point of retrocession, of AC and AB, the branches not passing beyond the point A.

OSCULATORY *Circle*, is the same as the circle of curvature; that is, the circle having the same curvature with any curve at a given point. See the foregoing article, Osculation, where BEG, in the last figure but one, is the osculatory circle of the curve AEF at the point E; and CE the osculatory radius, or the radius of curvature.

This circle is called osculatory, because that, of all the circles that can touch the curve in the same point, that one touches it the closest, or in such manner that no other tangent circle can be drawn between it and the curve; so that, in touching the curve, it embraces it as it were, both touching and cutting it at the same time, being on one side at the convex part of the curve, and on the other at the concave part of it.

In a circle, all the osculatory radii are equal, being the common radius of the circle; the evolute of a circle being only a point, which is its centre. See some properties of the osculatory circle in Maclaurin's Algebra, Appendix De Linearum Geometricarum Proprietatibus generalibus Tractatus, Theor. 2, § 15, &c, treated in a pure geometrical manner.

Osculatory *Parabola*. See Parabola.

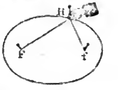
Osculatory *Point*, the osculation, or point of contact between a curve and its osculatory circle.

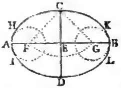
OSTENSIVE *Demonstrations*, such as plainly and directly demonstrate the truth of any proposition. In which they stand distinguished from apagogical ones, or reductions ad absurdum, or ad impossibile, which prove the truth proposed by demonstrating the absurdity or impossibility of the contrary.

OTACOUSTIC, an instrument that aids or improves the sense of hearing. See Acoustics.

OVAL, an oblong curvilinear figure, having two unequal diameters, and bounded by a curve line returning into itself. Or a figure contained by a single curve line, imperfectly round, its length being greater than its breadth, like an egg: whence its name. The proper oval, or egg-shape, is an irregular figure, being narrower at one end than at the other; in which it differs from the ellipse, which is the mathematical oval, and is equally broad at both ends. The common people confound the two together: but geometricians call the oval a false ellipse.

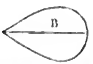
The method of describing an oval chiefly used among artificers, is by a cord or string, as F H f, whose length is equal to the greater diameter of the intended oval, and which is fastened by its extremes to two points or pins, F and f, planted in its longer diameter; then, holding it always stretched out as at H, with a pin or pencil carried round the inside, the oval is described: which will be so much the longer and narrower as the two fixed points are farther apart. This oval so described is the true mathematical ellipse, the points F and f being the two foci. But, in architectural designs, where great accuracy is required, the elliptic compasses are better employed. See Compasses *Elliptical*.

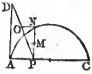




Another popular way to describe an oval of a given length and breadth, is thus:—Set the given length and breadth, AB and CD, to bisect each other perpendicularly at E; with the centre C, and radius AE, describe an arc to cross AB in F and G; then with these centres, F and G, and radii AF and BG, describe two little arcs HI and KL for the smaller ends of the oval; and lastly, with the centres C and D, and radius CD, describe the arcs HK and IL, for the flatter or longer sides of the oval. But this, it is evident, does not form a true ellipse. Sometimes other points, instead of C and D, are to be taken by trial, as centres in the line CD, produced if necessary, so as to make the two last arcs join best with the two former ones.

Oval denotes also certain roundish figures, of various and pleasant shapes, among curve lines of the higher kinds. These figures are expressed by equations of all dimensions above the 2d, and more especially the even dimensions, as the 4th, 6th, &c. Of this kind is the equation $a^2y^2 = -x^4 + ax^3$, which denotes the oval B, in shape of the



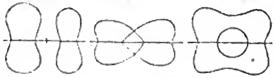


section of a pear through the middle, and is easily described by means of points. For, if a circle be described whose diameter AC is $= a$, and AD be perpendicular and equal to AC; then, taking any point P in AC, joining DP, and drawing PN parallel to AD, and NO parallel to AC; and lastly taking PM = NO, the point M will be one point of the oval sought.—In like manner the equation

$$y^4 - 4y^2 = -ax^4 + bx^3 + cx^2 + dx + e$$

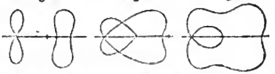
expresses several very pretty ovals, among which the following 12 are some of the most remarkable. For when the equation $ax^4 = bx^3 + cx^2 + dx + e$ has four real unequal roots, the given equation denotes the three following species, in fig. 1, 2, 3:

Fig. 1. Fig. 2. Fig. 3.



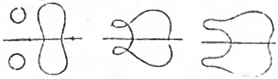
When the two less roots are equal, the three species will be expressed as in fig. 4, 5, 6, thus:

Fig. 4. Fig. 5. Fig. 6.



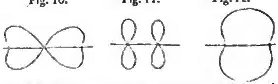
When the two less roots become imaginary, it will denote the three species exhibited in fig. 7, 8, 9:

Fig. 7. Fig. 8. Fig. 9.



When the two middle roots are equal, the species will be as appears in fig. 10: when two pair of roots are equal, the species will be as in fig. 11: and when the two middle roots become imaginary, the species will be as appears in fig. 12:

Fig. 10. Fig. 11. Fig. 12.



OUGHTRED (William), an eminent English mathematician and divine, was born at Eton in Buckinghamshire, 1573, and educated in the school there; whence he was elected to King's-college in Cambridge in 1592, where he continued about 12 years, and became a fellow; employing his time in close application to useful studies, particularly the mathematical sciences, which he contributed greatly, by his example and exhortation, to bring into vogue among his acquaintances there.

About 1603 he quitted the university, and was presented to the rectory of Aldbury, near Guildford in Surrey, where he lived a long retired and studious life, seldom travelling so far as London once a year; his recreation being a diversity of studies. "As often," says he, "as I was tired with the labours of my own profession, I have allayed that tediousness by walking in the pleasant, and more than Elysian Fields of the diverse and various parts of human learning, and not of the mathematics only." About the year 1628 he was appointed by the earl of Arundel tutor to his son lord William Howard, in the mathematics, and his Clavis was drawn up for the use of that young nobleman. He always held a correspondence by letters with many of the most eminent scholars of his time, on mathematical subjects: the originals of which were preserved, and communicated to the Royal Society, by William Jones, esq. The chief mathematicians of that age owed much of their skill to him; and his house was always full of young gentlemen who came from all parts to receive his instruction: nor was he without invitations to settle in France, Italy, and Holland. "He was as facetious," says Mr. David Lloyd, "in Greek and Latin, as solid in arithmetic, geometry, and the sphere, of all measures, music, &c; exact in his style as in his judgment; handling his tube and other instruments at 80 as steadily as others did at 30; owing this, as he said, to temperance and exercise; principling his people with plain and solid truths, as he did the world with great and useful arts; advancing new inventions in all things but religion, which he endeavoured to promote in its primitive purity, maintaining that prudence, meekness, and simplicity were the great ornaments of his life."

Notwithstanding Oughtred's great merit, being a strong royalist, he was in danger, in 1646, of a sequestration by the committee for plundering ministers; several articles being deposed and sworn against him: but, on his day of hearing, William Lilly, the famous astrologer, applied to sir Bulstrode Whitlocke and all his old friends; who appeared so numerous in his behalf, that though the chairman and many other presbyterian members were active against him, yet he was cleared by the majority. This is told us by Lilly himself, in the History of his own Life, where he styles Oughtred the most famous mathematician then of Europe.—He died in 1660, at 86 years of age, and was buried at Aldbury. It is said he died of a sudden ecstasy of joy, about the beginning of May, on hearing the news of the vote at Westminster, which passed for the restoration of Charles the 2d.—He left one son, whom he put apprentice to a watch-maker, and wrote a book of instructions in that art for his use.

He published several works in his life-time; the principal of which are the following:

1. Arithmeticæ in Numero et Speciebus Institutio, in 8vo, 1631. This treatise he intended should serve as a general key to the mathematics. It was afterwards reprinted, with considerable alterations and additions, in 1648, under the title of A Key to the Mathematics. It was also published in English, with several additional tracts; viz, one on the Resolution of all kinds of Affected Equations in Numbers; a second on Compound Interest; a third on the easy Art of Delineating all manner of Plain Sun-dials; also a Demonstration of the Rule of False-Position. A 3d edition of the same work was printed in 1652, in Latin, with the same additional tracts, together with some others, viz, On the Use of Logarithms; A Declaration of the 10th book of Euclid's Elements; a treatise on Regular Solids; and the Theorems contained in the books of Archimedes.

2. The Circles of Proportion, and a Horizontal Instrument; in 1633, 4to; published by his scholar Mr. William Foster.—3. Description and Use of the Double Horizontal Dial; 1636, 8vo.—4. Trigonometria: his treatise on Trigonometry, in Latin, in 4to, 1657: and another edition in English, together with Tables of Sines, Tangents, and Secants.

He left behind him a great number of papers on mathematical subjects; and in most of his Greek and Latin mathematical books, there were found notes in his own hand-writing, with an abridgment of almost every proposition and demonstration in the margin, which came into the museum of the late William Jones, esq. These books and manuscripts then passed into the hands of his friend sir Charles Scarborough the physician; the latter of which were carefully looked over, and all that were found fit for the press, printed at Oxford in 1676, in 8vo, under the title of

5. Opuscula Mathematica hactenus inedita. This collection contains the following pieces: (1) Institutiones Mechanicæ: (2) De Variis Corporum Generibus Gravitate et Magnitudine comparatis: (3) Automata: (4) Quæstiones Diophanti Alexandrini, libri tres: (5) De Triangulis Planis Rectangulis: (6) De Divisione Superficierum: (7) Musicæ Elementa: (8) De Propugnaculorum Munitionibus: (9) Sectiones Angulares.

6. In 1660, sir Jonas Moore annexed to his Arithmetic a treatise entitled, "Conical Sections; or, The several Sections of a Cone; being an Analysis or Methodical Contraction of the two first books of Mydorgius, and whereby the nature of the Parabola, Hyperbola, and Ellipsis, is very clearly laid down. Translated from the papers of the learned William Oughtred."

Oughtred, though undoubtedly a very great mathematician, was yet far from having the happiest method of treating the subjects he wrote upon. His style and manner were very concise, obscure, and dry; and his rules and precepts so involved in symbols and abbreviations, as rendered his mathematical writings very troublesome to read, and difficult to be understood. Besides the characters and abbreviations before made use of in algebra, he introduced several others; as

$\times$ to denote multiplication;
$::$ for proportion or similitude of ratios;
$\div\!\!\!\!:$ for continued proportion;
$\sqsupset$ $\sqsubset$ for greater and less;

OUNCE, a small weight, being the 16th part of a pound avoirdupois; and the 12th part of a pound troy.—The avoirdupois ounce is divided into 16 drachms or drams; also the ounce troy into 24 pennyweights, and the pennyweight into 24 grains.

OVOLO, in Architecture, a round moulding, whose profile or sweep, in the Ionic and composite capital, is usually a quadrant of a circle; whence it is also popularly called the quarter round.

OUTWARD *Flanking Angle*, or the *Angle of the Tenaille*, is that comprehended by the two flanking lines of defence.

OUTWORKS, in Fortification, all those works made on the outside of the ditch of a fortified place, to cover and defend it.—Outworks, called also advanced and detached works, are those which not only serve to cover the body of the place, but also to keep the enemy at a distance, and prevent them from taking advantage of the cavities and elevations usually found in the places about the counterscarp; which might serve them either as lodgments, or as rideaux, to facilitate the carrying on their trenches, and planting their batteries against the place. Such are ravelins, tenailles, hornworks, queue d'arondes, envelopes, and crownworks. Of these, the most usual are ravelins, or halfmoons, formed between the two bastions, on the flanking angle of the counterscarp, and before the curtain, to cover the gates and bridges.

It is a general rule in all outworks, that if there be several of them, one before another, to cover one and the same tenaille of a place, the nearer ones must gradually, and one after another, command those which are farthest advanced out into the campagne; that is, must have higher ramparts, that so they may overlook and fire upon the besiegers, when they are masters of the more outward works. The gorges also of all outworks should be plain, and without parapets; lest, when taken, they should serve to secure the besiegers against the fire of the retiring besieged; whence the gorges of outworks are only palisadoed, to prevent a surprise.

OX-EYE, in Optics. See SCIOPTIC, and CAMERA *Obscura*

OXGANG, or OXGATE, of land, is usually taken for 15 acres; being as much land as it is supposed one ox can plow in a year. In Lincolnshire they still corruptly call it oskin of land.—In Scotland, the term is used for a portion of arable land, containing 13 acres.

OXYDS, a compound of oxygen and some other body, in such proportion as not to produce an acid.

OXYGEN, a certain simple substance that enters into the composition of water and air; being that which generates or produces acids.

This, one of the most characteristic properties of this body, was discovered by Dr. Priestley in 1774. It was at first called dephlogisticated air, and afterwards successively known by the names of eminently respirable air, pure air, vital air, as long as it was not known that this aerial form is merely one of its states of combination. As soon as this truth was well proved, and clearly explained by Lavoisier, it appeared necessary to give it a new name, which might be applicable to all the states in which it could exist, as well that of gas as of the liquid or solid form; and it finally received the name of Oxygen.

Oxygen, like many other natural bodies, is found in three states, but in none of them is it alone or insulated. In the gaseous form it is dissolved in caloric; in the liquid and solid form it is combined with different substances. As oxygen is often contained, in a more or less solid form, in several natural fossils, which have undergone combustion, and as it has much attraction for caloric, it is only requisite that some one of those fossils should be heated more or less, in order to disengage this principle, and obtain it in the form of gas or air. Thus, the chemists expose certain substances, particularly metals burned by nature or art, to an active fire in close vessels, so disposed as to conduct and receive, under inverted jars, the gas or elastic fluid to be collected; which is thus the product of a true combustion.

The two chief sources from which oxygen is derived, (each of them immense in extent,) are water and air. In the former it is condensed into a liquid form, and combined with about a third of its weight of hydrogen; in the latter it is united with azot, and forms rather more than $\frac{1}{4}$ part of the atmosphere.—There are various other smaller sources of oxygen, such as many parts of the organized world, vegetable or animal (independently of the water they contain so abundantly), mineral acids, and metallic oxyds, &c; but the quantities from these last sources are exceedingly small, in comparison with the preceding.—Most of the green parts of vegetables, while living, yield oxygen gas when exposed to the sun's rays.—The purest possible oxygen gas is obtained by a higher degree of voltaic electricity, from such substances as it is capable of completely decomposing. One of the next purest oxygen gases is obtained by distilling, per se, the dry oxymuriat of potash.

The black oxyd of manganese contains a great quantity of oxygen so loosely combined, as to be expelled by a moderate red heat; and this is the method usually pursued: an earthen or iron retort is filled with the black oxyd of manganese in powder, and heated in a brisk fire. The first product of gas comes over when the manganese is faintly red, and consists chiefly of carbonic acid, so that a taper is immediately extinguished. After this, if small samples of the gas be examined as it comes over, by dipping a bit of kindled wood in it, the fire will soon be found to burn with increased flame and brightness, a sign of the presence of oxygen; soon after which it may be collected for use. If the manganese be very good, one pound of it will yield 1400 cubic inches of great purity; that is, containing no more than $\frac{1}{10}$ of carbonic acid or any other gas.—Manganese, if moistened with sulphuric acid, will also give out much oxygen, on applying no greater heat than that of a taper; and it may thus be obtained very expeditiously, with the simplest apparatus possible.

All the oxyds of mercury, when heated red hot, are decomposed, the metals return to the state of running mercury (which is driven up in vapour and soon condenses), and the oxygen which it contained appears in the gaseous form, mixed with any acid which may have existed in the oxyd.—Oxygen gas may also be obtained very cheap, and considerably pure, by the destructive distillation of nitre in a moderate red heat.—The burning of the several combustible bodies in oxygen gas, forms a number of most beautiful and instructive experiments, and has contributed more than any thing else to give accurate ideas on the nature of combustion in general.

The characters that peculiarly distinguish oxygen gas, are the eminent degree in which it supports combustion and respiration; it being proved that neither of these can continue without oxygen, and that it is solely owing to *its* presence that atmospheric air, and the other compound gasses, are fitted for maintaining those grand processes of the material world. If a small animal be immersed in oxygen gas, it will live much longer than in the same quantity of common air; and if the carbonic acid, generated in the process, be occasionally removed by alkalies, the animal will remain in the gas uninjured for a much longer time. In this, and in many other respects, the process of respiration and combustion agree; but still there are some circumstances which render it probable that the diluted state of oxygen (such as it exists in common air) is altogether fitter for animal respiration, than a purer oxygen.

OXYGONE, in Geometry, is acute-augled, meaning a figure consisting wholly of acute angles, or such as are less than 90 degrees each.—The term is chiefly applied to triangles, where the three angles are all acute.

OXYGONIAL, is acute-angular.

OXYMURIATIC Acid, is the same as dephlogisticated muriatic acid, nr chlorine.

OZANAM (James), an eminent French mathematician, was descended from a family of Jewish extractinn, but which had long been converts to the Romish faith; and some of whom had held considerable places in the parliaments of Provence. He was born at Boligneux in Bressia, in the year 1640; and being a younger son, though his father had a good estate, it was thought proper to educate him for the church, that he might enjoy some small benefices which belonged to the family, to serve as a provision for him. Accordingly he studied divinity four years; but then, on the death of his father, he devoted himself entirely to the mathematics, to which he had always been strongly attached. Some mathematical books, which fell into his hands, first excited his curiosity; and by his extraordinary genius, without the aid of a master, he made so great a progress, that at the age of 15 he wrote a treatise on that subject.

For a maintenance he first went to Lyons to teach the mathematics, which answered very well; but his generous disposition procured him still better success elsewhere. Among his scholars were two foreigners, who expressing their uneasiness to him, at being disappointed of some bills of exchange for a journey to Paris; he asked them how much would do, and being told 50 pistoles, he lent them the money immediately, even without their note for it. On their arrival at Paris, mentioning this generous action to M. Daguesseau, father of the chancellor, this magistrate was so pleased with it, that he engaged them to invite Ozanam to Paris, with a promise of his favour. The opportunity was eagerly embraced; and the business of teaching the mathematics here soon brought him in a considerable income: but he wanted prudence for some time to make the best use of it. He was young, handsome, and sprightly; and much addicted both to gaming and gallantry, which continually drained his purse. However, this expense in time led him to think of matrimony, and he soon after married a young woman without a fortune. She made amends for this defect however by her modesty, virtue, and sweet temper; so that though the state of his purse was not amended, yet he had more real enjoyment than before, being indeed completely happy in her, as long as she lived. He had twelve children by this lady, though most of them died young; and he was lastly rendered quite unhappy by the death of his wife also, which happened in 1701. Neither did this misfortune come single: for the war breaking out about the same time, on account of the Spanish succession, it swept away all his scholars, who being foreigners, were obliged to leave Paris. Thus he sunk into a very melancholy state; under which however he received some relief, and amusement, from the honour of being admitted this same year an elève of the Royal Academy of Sciences. But he never recovered his wonted health and spirits; so that, though he lingered through a few dull years, with a strong presentiment of his approaching dissolution, he might rather be said to exist than to live, until the year 1717, when he was seized with an apoplexy, which terminated his existence on the 3d of April, at 77 years of age.

Ozanam possessed a mild and calm disposition, a cheerful and pleasant temper, an inventive genius, and a generosity almost unparalleled. After marriage his conduct was irreproachable; and at the same time that he was sincerely pious, he had a great aversion to disputes about theology. On this subject he used to say, that it was the business of the Sorbonne doctors to discuss, of the pope to decide, and of a mathematician to go straight to heaven in a perpendicular line.—He wrote a great number of useful books; a list of which is as follows:

1. A treatise of Practical Geometry; 12mo, 1684.—2. Tables of Sines, Tangents, and Secants; with a treatise on Trigonometry; 8vo, 1685.—3. A treatise of Lines of the First Order; of the Construction of Equations; and of Geometric Lines, &c; 4to, 1687.—4. The Use of the Compasses of Proportion, &c; with a treatise on the Division of Lands; 8vo, 1688.—5. An Universal Instrument for readily resolving Geometrical Problems without calculation; 12mo, 1688.—6. A Mathematical Dictionary; 4to, 1690.—7. A General Method for drawing Dials, &c, 12mo, 1693.—8. A Course of Mathematics, in 5 volumes, 8vo, 1693.—9. A treatise on Fortification, Ancient and Modern; 4to, 1693.—10. Boulanger's treatise on the Sphere corrected and enlarged; 12mo.

Ozanam has also the following pieces in the Journal des Sçavans: viz, (1) Demonstration of this theorem, that neither the Sum nor the Difference of two Fourth Powers, can be a Fourth Power; journal of May 1680.—(2) Answer to a Problem proposed by M. Comiers; journal of Nov. 17, 1681.—(3) Demonstration of a Problem concerning False and Imaginary Roots; journal of April 2 and 9, 1685.—(4) Method of finding in Numbers the Cubic and Sursolid Roots of a Binomial, when it has one; journal of April 9, 1691.

Also in the Memoires de Trevoux, of December 1703, he has this piece, viz, Answer to certain articles of Objection to the first part of his Algebra. And lastly, in the Memoirs of the Academy of Sciences, of 1707, he has Observations on a Problem of Spherical Trigonometry.

P.

PACE, or *Geometrical Pace*, an uncertain lineal measure, by some supposed to be equal to 5 feet, by others 4¼, &c.

PAGAN (BLAISE FRANÇOIS Comte de), an eminent French mathematician and engineer, was born at Avignon in Provence, 1604; and entered on the profession of a soldier at 14 years of age. In 1620 he was employed at the siege of Caen, in the battle of Pont de Cé, with the reduction of the Navarreins, and the rest of Béarn; where he signalized himself, and acquired a reputation far above his years. He was present, in 1621, at the siege of St. John d'Angeli, as also that of Clarac and Montauban, where he lost an eye by a musket-shot. After this time, there happened neither siege, battle, nor any other occasion, in which he did not signalize himself by some effort of courage and conduct. At the passage of the Alps, and the barricade of Suza, he put himself at the head of the forlorn hope, composed of the bravest youths among the guards; and undertook to arrive the first at the attack, by a private way which was extremely dangerous; when, having gained the top of a very steep mountain, he cried out to his followers, "There lies the way to glory!" On which, sliding along this mountain, they came first to the attack; when immediately commencing a furious onset, and the army coming to their assistance, they forced the barricades. When the king laid siege to Nancy in 1633, Pagan attended him, in drawing the lines and forts of circumvallation.—In 1642 he was sent to the service in Portugal, as field-marshal; and the same year he unfortunately lost the sight of his other eye by a distemper, and thus became totally blind.

But though he was thus prevented from serving his country with his conduct and courage in the field, he resumed the vigorous study of fortification and the mathematics; and in 1645 he gave the public a treatise on the former subject, which was esteemed the best extant.—In 1651 he published his Geometrical Theorems, which showed an extensive and critical knowledge of his subject. —In 1655 he printed a Paraphrase of the Account of the River of Amazons, by father de Rennes; and, though blind, it is said he drew the chart of the river and the adjacent parts of the country, as in that work.—In 1657 he published The Theory of the Planets, cleared from that multiplicity of excentric cycles and epicycles, which the astronomers had invented to explain their motions. This work distinguished him among astronomers, as much as that of Fortification had among engineers. And in 1658 he printed his Astronomical Tables, which are plain and succinct.

Few great men are without some foible: Pagan's was that of a prejudice in favour of judicial astrology; and though he is more reserved than most others on that head, yet we cannot place what he did on that subject among those productions which do honour to his understanding. He was beloved and respected by all persons illustrious for rank as well as science; and his house was the rendezvous of all the polite and learned both in city and court. —He died at Paris, universally regretted, Nov. 18, 1665, at 61 years of age.

Pagan had a universal genius; and, having turned his attention chiefly to the art of war, and particularly to the branch of fortification, he made extraordinary progress and improvements in it. He understood mathematics not only better than is usual for a gentleman whose view is to push his fortune in the army, but even to a degree superior to that of the ordinary masters who teach that science. He had so particular a genius for this kind of learning, that he acquired it more readily by meditation than by reading authors upon it; and accordingly he spent less time in such books than he did in those of history and geography. He had also made morality and politics his particular study; so that he may be said to have drawn his own character in his Homme Heroïque, and to have been one of the completest gentlemen of his time. Having never married, that branch of his family, which removed from Naples to France in 1552, became extinct in his person.

PALILICUM, the same as Aldebaran, a fixed star of the first magnitude, in the eye of Taurus, the Bull.

PALISADES, or PALISADOES, in Fortification, stakes or small piles driven into the ground, in various situations, as some defence against the surprise of an enemy. They are usually about 6 or 7 inches square, and 9 or 10 feet long, driven about 3 feet into the ground, and 6 inches apart from each other, being braced together by pieces nailed across them near the tops; and secured by thick posts at the distance of every 4 or 5 yards.

PALISADES are placed in the covert-way, parallel to and at 3 feet distance from the parapet or ridge of the glacis, to secure it against a surprise. They are also used to fortify the avenues of open forts, gorges, half-moons, the bottoms of ditches, the parapets of covert-ways; and in general all places liable to surprise, and easy of access.

PALISADOES are usually planted perpendicularly; though some make an angle inclining out towards the enemy, that the ropes cast over them, to tear them up, may slip.

PALLADIO (ANDREW), a celebrated Italian architect in the 16th century, was a native of Vicenza in Lombardy, and the disciple of Triffin, a learned Patrician, or Roman nobleman of that town. Palladio was one of those who laboured particularly to restore the ancient beauties of architecture, and contributed greatly to revive a true taste in that art. Having learned the principles of it, he went to Rome; where, applying himself with great diligence to study the ancient monuments, he entered into the spirit of their architects, and possessed himself of all their beautiful ideas. This enabled him to restore their rules, which had been corrupted by the barbarous Goths. He made exact drawings of the principal works of antiquity which were to be met with at Rome; to which he added Commentaries, which went through several impressions, with the figures. This, though a very useful work, is greatly exceeded by the 4 books of architecture which he published in 1570. The last book treats of the Roman temples, and is executed in such a manner, as gives him the preference to all his predecessors on that subject. It was tranlated into French by Roland Friatt, and into

English by several authors. Inigo Jones wrote some excellent remarks upon it, which were published in an edition of Palladio by Leoni, 1742, in 2 volumes folio. Palladio died in 1580.

PALLAS, is the name given by Dr. Olbers to a new planet discovered by him at Bremen, March 28, 1802, being now the 7th in order from the sun, and distant from him about 263 million miles: it performs its periodic revolution in 1682 days, or 4 years 7 months 11 days; but it is too small to be perceived by the naked eye, or even with the assistance of a telescope of an inferior kind. Its elements, as far as they have been at present ascertained, are stated below, but it is probable that future observations may show them to stand in need of some corrections.

Revolution in its orbit 4 years 7 months 11 days.

Mean longitude Jan. 1st, 1804	9^s	29°	53′
Annual motion	2	18	11
Aphelion	10	1	7
Node	5	22	28
Excentricity		0·2463	
Inclination		34	39

PALLETS, in Clock and Watch Work, are those pieces or levers which are connected with the pendulum or balance, and receive the immediate impulse of the swing-wheel, or balance-wheel, so as to maintain the vibrations of the pendulum in clocks, and of the balance in watches. —The pallets in all the ordinary constructions of clocks and watches, are formed on the verge or axis of the pendulum or balance, and are of various lengths and shapes, according to the construction of the piece, or the fancy of the artist.

PALLIFICATION, or PILING, in Architecture, denotes the piling of the ground-work, or the strengthening it with piles, or timber driven into the ground; which is practised when buildings are erected on a moist or marshy soil.

PALLISADES. See PALISADES.

PALM, an ancient long-measure, taken from the extent of the hand.—The Roman palm was of two kinds: the great palm, taken from the length of the hand, answered to our span, and contained 12 fingers, digits, or fingers breadths, or 9 Roman inches, equal to about 8½ English inches. The small palm, taken from the breadth of the hand, contained 4 digits or fingers, equal to about 3 English inches.—The Greek palm, or doron, was also of two kinds. The small contained 4 fingers, equal to little more than 3 inches. The great palm contained 5 fingers. The Greek double palm, called dichas, contained also in proportion.

The modern palm is different in different places where it is used. It contains,

	Inc.	Lines
At Rome	8	3½
At Naples, according to Riccioli,	8	0
Ditto, according to others,	8	7
At Genoa	9	9
At Morocco and Fez	7	2
Languedoc, and some other parts of France,	9	9
The English palm is	3	0

PALM-SUNDAY, the last sunday in lent, or the sunday next before easter day. So called, from the primitive days, on account of a pious ceremony then in use, of bearing palms, in memory of the triumphant entry of Jesus Christ into Jerusalem, 8 days before the feast of the passover.

PAPPUS, a very eminent Greek mathematician of Alexandria towards the latter part of the 4th century, particularly mentioned by Suidas, who says he flourished under the emperor Theodosius the Great, who reigned from the year 379 to 395 of Christ. His writings indicate him to have been a consummate mathematician. Many of his works are lost, or at least have not yet been discovered. Suidas mentions several of his works, as also Vossius De Scientiis Mathematicis. The principal of these are, his Mathematical Collections, in 8 books, the first and part of the second being lost. He wrote also a Commentary on Ptolemy's Almagest; a Universal Chorography; A Description of the Rivers of Libya; A Treatise of Military Engines; Commentaries on Aristarchus of Samos, concerning the Magnitude and Distance of the Sun and Moon; &c. Of these, there have been published, The Mathematical Collections, in a Latin translation, with a large Commentary, by Commandine, in folio, 1588; and a second edition of the same in 1660. In 1644, Mersenne exhibited a kind of abridgment of them in his Synopsis Mathematica, in 4to: but this contains only such propositions as could be understood without figures. In 1655, Meibomius gave some of the Lemmata of the 7th book, in his Dialogue on Proportions. In 1688, Dr. Wallis printed the last 12 propositions of the 2d book, at the end of his Aristarchus Samius. In 1703, Dr. David Gregory gave part of the preface of the 7th book, in the Prolegomena to his Euclid. In 1706, Dr. Halley gave that Preface entire, in the beginning of his Apollonius. And lastly, the reverend and learned Dr. Trail (in an appendix to his Account of the Life and Writings of Rob. Simson, M. D.) has added a critical account of the Mathematical Collections of this author.

As the contents of the principal work, the Mathematical Collections, are exceedingly curious, and no account of them having ever appeared in English when this was written, I shall here give a very brief analysis of those books, extracted from my notes on this author.

Of the Third Book—The subjects of the third book consist chiefly of three principal problems; for the solution of which, a great many other problems are resolved, and theorems demonstrated. The first of these three problems is, To find Two Mean Proportionals between two given lines—The 2d problem is, To find, what are called, three Medietates in a semicircle; where, by a Medietas is meant a set of three lines in continued proportion, whether arithmetical, or geometrical, or harmonical; so that to find three medietates, is to find an arithmetical, a geometrical, and an harmonical set of three terms each. And the third problem is, From some points in the base of a triangle, to draw two lines to meet in a point within the triangle, so that their sum shall be greater than the sum of the other two sides that are without them. A great many curious properties are premised to each of these problems; then their solutions are given according to the methods of several ancient mathematicians, with an historical account of them, and his own demonstrations; and lastly, their applications to various matters of great importance. In his historical anecdotes, many curious things are preserved concerning mathematicians that were ancient even in his time, which we should otherwise have known nothing at all about.

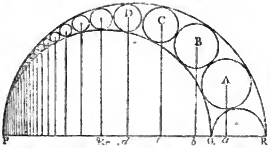
In order to the solution of the first of the three problems above mentioned, he begins by premising four general theorems concerning proportions. Then follows a dissertation on the nature and division of problems by the ancients, into Plane, Solid, and Linear, with examples of them, taken from the writings of Eratosthenes, Philo, and Hero. A solution is then given to the problem concerning two mean proportionals, by four different ways, namely, according to Eratosthenes, Nicomedes, Hero, and after a way of his own, in which he not only doubles the cube, but also finds another cube in any proportion whatever to a given cube.

For the solution of the second problem, he lays down very curious definitions and properties of Medietates of all kinds, and shows how to find all in a great variety of cases, both as to what the ancients had done in them, and what was done by others whom he calls the moderns. Medietas seems to have been a general term invented to express three lines, having either an arithmetical, or a geometrical, or an harmonical relation; for the words proportion (or ratio), and analogy (or similar proportions), are restricted to a geometrical relation only. But he shows how all the medietates may be expressed by analogies.

The solution of the 3d problem leads Pappus to the consideration of a number of admirable and seemingly paradoxical problems, concerning the inflecting of lines to a point within triangles, quadrangles, and other figures, the sum of which shall exceed the sum of the surrounding exterior lines.

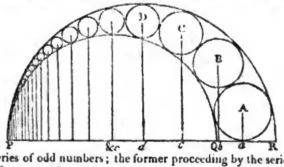
Finally, a number of other problems are added, concerning the inscription of all the regular bodies within a sphere. The whole being effected in a very general and purely mathematical way; making all together 58 propositions, viz, 44 problems and 14 theorems.

Of the 4th Book of Pappus.—In the 4th book are first premised a number of theorems relating to triangles, parallelograms, circles, with lines in and about circles, and the tangencies of various circles: all preparatory to this curious and general problem, viz, relative to an infinite series of circles inscribed in the space, called αρβελον, Arbelon, contained between the circumferences of two circles touching inwardly. Where it is shown, that if the infinite series of circles be inscribed in the manner of this first figure, where three semicircles are described on the lines PR, PQ, QR, and the perpendiculars A*a*, B*b*, C*c*,



&c, let fall from the centres of the series of inscribed circles; then the property of these perpendiculars is this, viz, that the first perpendicular A*a* is equal to the diameter or double the radius of the circle A; the second perpendicular B*b* equal to double the diameter or 4 times the radius of the second circle B; the third perpendicular C*c* equal to 3 times the diameter or 6 times the radius of the third circle C; and so on, the series of perpendiculars being to the series of the diameters, as 1, 2, 3, 4, &c, to 1, or to the series of radii, as 2, 4, 6, 8, &c, to 1.

But if the several small circles be inscribed in the manner of this second figure, the first circle of the series touching the part of the line QR; then the series of perpendiculars A*a*, B*b*, C*c*, &c, will be 1, 3, 5, 7, &c, times the radii of the circles A, B, C, D, &c; viz, according to the



series of odd numbers; the former proceeding by the series of even numbers.

Pappus next treats of the Helix, or Spiral, proposed by Conon, and resolved by Archimedes, demonstrating its principal properties: in the demonstration of some of which, he makes use of the same principles as Cavallerius did lately, adding together an infinite number of infinitely short parallelograms and cylinders, which he imagines a triangle and cone to be composed of.—He next treats of the properties of the Conchoid, which Nicomedes invented for doubling the cube; applying it to the solution of certain problems concerning Inclinations, with the finding of two mean proportionals, and cubes in any proportion whatever.—Then of the τετραγωνιζουσα, or Quadratrix, so called from its use in squaring the circle, for which purpose it was invented and employed by Dinostratus, Nicomedes, and others: the use of which however he disapproves, as it requires postulates equally hard to be granted, as the problem itself to be demonstrated by it. —Next he treats of Spirals, described on planes, and on the convex surfaces of various bodies.—From another problem, concerning Inclinations, he shows, how to trisect a given angle; to describe an hyperbola, to two given asymptotes, and passing through a given point; to divide a given arc or angle in any given ratio; to cut off arcs of equal lengths from unequal circles; to take arcs and angles in any proportion, and arcs equal to right lines; with parabolic and hyperbolic loci, which last is one of the inclinations of Archimedes.

Of the 5th Book of Pappus.—This book opens with reflections on the different natures of men and brutes, the former acting by reason and demonstration, the latter by instinct, yet some of them with a certain portion of reason or foresight, as bees, in the curious structure of their cells, which he observes are of such a form as to complete the space quite around a point, and yet require the least materials to build them, to contain the same quantity of honey. He shows that the triangle, square, and hexagon, are the only regular polygons capable of filling the whole space round a point; and remarks that the bees have chosen the fittest of these; proving afterwards, in the propositions, that of all regular figures of the same perimeter, that is of the largest capacity which has the greatest number of sides or angles, and consequently that the circle is the most capacious of all figures whatever.

And thus he finishes this curious book on Isoperimetrical figures, both plane and solid; in which many curious and important properties are strictly demonstrated, both of planes and solids, some of them being old in his time, and many new ones of his own. In fact, it seems he has here brought together into this book, all the properties relating to isoperimetrical figures then known, and their different degrees of capacity. In the last theorem of the book, he has a dissertation to show, that there can be no more regular bodies besides the five Platonic ones, or, that only the regular triangles, squares, and pentagons, will form regular solid angles.

Of the 6th Book of Pappus.—In this book he treats of certain spherical properties, which had been either neglected, or improperly and imperfectly treated by some celebrated authors before his time.—Such are some things in the 3d book of Theodosius's Spherics, and in his book on Days and Nights, as also some in Euclid's Phenomena. For the sake of these, Pappus premises and intermixes many curious geometrical properties, especially of circles of the sphere, and spherical triangles. He adverts to some curious cases of variable quantities; showing how some increase and decrease both ways to infinity; while others proceed only one way by increase or decrease, to infinity, and the other way to a certain magnitude; and others again both ways to a certain magnitude, giving a maximum and minimum.—Here are also some curious properties concerning the perspective of the circles of the sphere, and of other lines. Also the locus is determined of all the points from whence a circle may be viewed, so as to appear an ellipse, whose centre is a given point within the circle; which locus is shown to be a semicircle passing through that point.

Of the 7th Book of Pappus.—In the introduction to this book, he describes very particularly the nature of the mathematical composition and resolution of the ancients, distinguishing the particular process and uses of them, in the demonstration of theorems and solution of problems. He then enumerates all the analytical books of the ancients, or those proceeding by resolution, which he does in the following order, viz, 1st, Euclid's Data, in one book: 2d, Apollonius's Section of a Ratio, 2 books: 3d, his Section of a Space, 2 books: 4th, his Tangencies, 2 books: 5th, Euclid's Porisms, 3 books: 6th, Apollonius's Inclinations, 2 books: 7th, his Plane Loci, 2 books: 8th, his Conics, 8 books: 9th, Aristæus's Solid Loci, 5 books: 10th, Euclid's Loci in Superficies, 2 books; and 11th, Eratosthenes's Medietates, 2 books. So that all the books are 31, the arguments or contents of which he exhibits, with the number of the loci, determinations, and cases, &c; with a multitude of lemmas and propositions laid down and demonstrated; the whole making 238 propositions, of the most curious geometrical principles and properties, relating to those books.

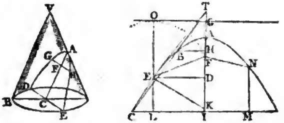
Of the 8th Book of Pappus.—The 8th book is altogether on Mechanics. It opens with a general oration on the subject of mechanics; defining the science, enumerating the different kinds and branches of it, and giving an account of the chief authors and writings on it. After an account of the centre of gravity, on which the science of mechanics so greatly depends, he shows, in the first proposition, that such a point really exists in all bodies. Some of the following propositions are also concerning the properties of the centre of gravity. He next comes to the inclined plane, and in prop. 9, shows what power will draw a given weight up a given inclined plane, when the power is given which can draw the weight along a horizontal plane. In the 10th prop. concerning the moving a given weight with a given power, he treats of what the ancients called a Glossocomum, which is nothing more than a series of wheels-and-axles, in any proportions, turning each other, till we arrive at the given power. In this proposition, as well as in several other places, he refers to some books that are now lost; as Archimedes on the Balance, and the Mechanics of Hero and of Philo. Then, from prop. 11 to prop. 19, he treats on various miscellaneous subjects, as, the organical construction of solid problems; the diminution of an architectural column; to describe an ellipse through five given points; to find the axis of an ellipse organically; to find also organically, the inclination of one plane to another, the nearest point of a sphere to a plane, the points in a spherical surface cut by lines joining certain points, and to inscribe seven hexagons in a given circle. Prop. 20, 21, 22, 23, teach how to construct and adapt the Tympani, or wheels of the glossocomum, to one another, showing the proportions of their diameters, the number of their teeth, &c. And prop. 24 shows how to construct the spiral threads of a screw.

He comes then to the five mechanical powers, by which a given weight is moved by a given power. He here proposes briefly to show what has been said of these powers by Hero and Philo, adding also some things of his own. Their names are, the axis-in-peritrochio, the lever, pulley, wedge, and screw; and he observes, those authors showed how they are all reduced to one principle, though their figures be very different. He then treats of each of these powers separately, giving their figures and properties, their construction and uses.

He next describes the manner of drawing very heavy weights along the ground, by the machine termed Chelone, which is a kind of sledge placed upon two loose rollers, and drawn forward by any power whatever, a third roller being always laid under the fore part of the chelone, as one of the other two is quitted and left behind by the motion of the machine. In fact, this is the same machine as has always been employed on many occasions, in moving very great weights to moderate distances.

Finally, Pappus describes the manner of raising great weights to any proposed height by the combination of mechanic powers, as, by cranes and other machines; illustrating this, and the former parts, by drawings of the machines that are described.

PARABOLA, in Geometry, a figure arising from the section of a cone, when cut by a plane parallel to one of its sides, as the section ADE parallel to the side VB of the cone. See CONIC *Sections*, where some general properties are given.



Some other Properties of the Parabola.—1. From the same point of a cone only one parabola can be drawn; all the other sections between the parabola and the parallel side of the cone being ellipses, and all without them hyperbolas. The parabola has but one focus, through which the axis AC passes; all the other diameters being parallel to this, and also infinite in length.

2. The parameter of the axis is a third proportional to any absciss and its ordinate; viz, AC : CD : : CD : *p*

the parameter. And therefore if x denote any absciss AC, and y the ordinate CD, it will be $x : y :: y : p = \frac{y^2}{x}$ the parameter; or, by multiplying extremes and means $px = y^2$, which is the equation of the parabola.

3. The focus F is the point in the axis where the double ordinate GH is equal to the parameter. Therefore, in the equation of the curve $px = y^2$, taking $p = 2y$, it becomes $2yx = y^2$, or $2x = y$, that is $2AF = FH$, or $AF = \frac{1}{2}FH$, or the focal distance from a vertex AF is equal to half the ordinate there, or $= \frac{1}{4}p$, one-fourth of the parameter.

4. The abscisses of a parabola are to one another, as the squares of their corresponding ordinates. This is evident from the general equation of the curve $px = y^2$, where, p being constant, x is as y^2.

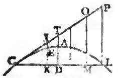
5. The line FE (fig. 2 above) drawn from the focus to any point of the curve, is equal to the sum of the focal distance and the absciss of the ordinate to that point; that is $FE = FA + AD = GD$, taking $AG = AF = \frac{1}{4}p$. Or EF is always $=$ EO, drawn parallel to DG, to meet the perpendicular GO, called the directrix.

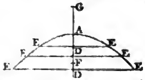
6. If a line TBC cut the curve of a parabola in two points, and the axis produced in T, and BH and CI be ordinates at those two points; then is AT a mean proportional between the abscisses AH and AI, or $AT^2 = AH . AI$. —And if TE touch the curve in E, then is $AT = AD =$ the mean between AH and AI.

7. If FE be drawn from the focus to the point of contact of the tangent TE, and EK perpendicular to the same tangent; then is $FT = FE = FK$; and the subnormal DK equal to the constant quantity $2AF$ or $\frac{1}{2}p$.

8. The diameter EL being parallel to the axis AK, the perpendicular EK, to the curve or tangent at E, bisects the angle LEF. And therefore all rays of light LE, MN, &c, coming parallel to the axis, will be reflected into the point F, which is therefore called the focus, or burning point; for the angle of incidence LEK is $=$ the angle of reflection KEF.

9. If IEK (next fig. below) be any line parallel to the axis, limited by the tangent TC and ordinate CKL to the point of contact; then shall $IE : EK :: CK : KL$. And the same thing holds true when CL is also in any oblique position.





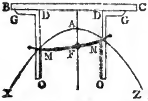
10. The external parts of the parallels IE, TA, ON, PL, &c, are always proportional to the squares of their intercepted parts of the tangent; that is,
the external parts IE, TA, ON, PL,
are proportional to CI^2, CT^2, CO^2, CP^2,
or to the squares CK^2, CD^2, CM^2, CL^2.
A property from which is immediately derived the common theory of projectiles.

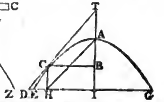
And as this property is common to every position of the tangent, if the lines IE, TA, ON, &c, be appended to the points I, T, O, &c, of the tangent, and moveable about them, and of such lengths as that their extremities E, A, N, &c, &c, be in the curve of a parabola in any one position of the tangent; then making the tangent revolve about the point C, the extremities E, A, N, &c, will always form the curve of some parabola, in every position of the tangent.

The same properties too that have been shown of the axis and its abscisses and ordinates, &c, are true of those of any other diameter. All which, besides many other curious properties of the parabola, may be seen demonstrated in my Treatise on Conic Sections, and in the Course of Mathematics.

11. *To Construct a Parabola by Points.*—In the axis produced take $AG = AF$ (last fig. above) the focal distance, and draw a number of lines EE, EE, &c, perpendicular to the axis AD; then with the distances GD, GD, &c, as radii, and the centre F, describe arcs crossing the parallel ordinates in E, E, &c. Then with a steady hand, or by the side of a slip of bent whale-bole, draw the curve through all the points E, E, E, &c.

12. *To describe a Parabola by a continued Motion.*—If the rule or the directrix BC be laid upon a plane, (first fig. below) with the square GDO, in such manner that one of its sides DG lies along the edge of that rule; and if the thread FMO equal in length to DO, the other side of the square, have one end fixed in the extremity of the rule at O, and the other end in some point F: then slide the side of the square DG along the rule BC, and at the same time keep the thread continually tight by means of the pin M, with its part MO close to the side of the square DO; so shall the curve AMX, which the pin describes by this motion, be one part of a parabola.—And if the square be turned over, and moved on the other side of the fixed point F, the other part of the same parabola AMZ will be described.





13. *To draw Tangents to the Parabola.*—If the point of contact C be given: (last fig. above) draw the ordinate CB, and produce the axis till AT be $=$ AB; then join TC, which will be the tangent.

14. Or if the point be given in the axis produced: take $AB = AT$, and draw the ordinate BC, which will give C the point of contact; to which draw the line TC as before.

15. If D be any other point, neither in the curve nor in the axis produced, through which the tangent is to pass: draw DEG perpendicular to the axis, and take DH a mean proportional between DE and DG, and draw HC parallel to the axis; so shall C be the point of contact, through which and the given point D the tangent DCT is to be drawn.

16. When the tangent is to make a given angle with the ordinate at the point of contact: take the absciss AI equal to half the paramater, or to double the focal distance, and draw the ordinate IE: also draw AH to make with AI the angle HAI equal to the given angle; then draw HC parallel to the axis, and it will cut the curve in C the point of contact, where a line drawn to make the given angle with CB will be the tangent required.

17. *To find the Area of a Parabola.* Multiply the base EG by the perpendicular height AH, and $\frac{2}{3}$ of the product will be the area of the space AEGA; because the parabolic space is $\frac{2}{3}$ of its circumscribing parallelogram.

18. *To find the Length of the Curve* AC, commencing at

the vertex.—Let y = the ordinate BC, p = the parameter, $q = \frac{2y}{p}$, and $s = \sqrt{(1+q^2)}$; then shall $\frac{1}{4}p \times (qs +$ hyp. log, of $q + s)$ be the length of the curve AC.

See various other rules for the areas, and lengths of the curve, &c, in my Treatise on Mensuration, sec 6, pa. 271, &c, 4th edition.

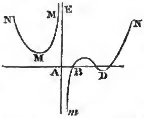
PARABOLAS *of the Higher Kinds*, are algebraic curves, defined by the general equation $a^{n-1}x = y^n$; that is, either $a^2x = y^3$, or $a^3x = y^4$, or $a^4x = y^5$, &c.

Some call these by the name of paraboloids: and in particular, if $a^2x = y^3$, it is called a cubical paraboloid; if $a^3x = y^4$, it is a biquadratical paraboloid, or a sursolid paraboloid. In respect of these, the parabola of the first kind, above explained, is called the Apollonian, or quadratic parabola.

Those curves are also to be referred to parabolas, that are expressed by the general equation $ax^{n-1} = y^n$, where the indices of the quantities on each side are equal, as before; and these are called semi-parabolas: as $ax^2 = y^3$ the semi-cubical parabola; or $ax^3 = y^4$ the semi-biquadratical parabola; &c.

They are all comprehended under the more general equation $a^m x^n = y^{m+n}$, where the two indices on one side are still equal to the index on the other side of the equation; which include both the former kinds of equations, as well as such as these following ones, viz, $a^2x^2 = y^4$, or $a^2x^3 = y^5$, or $a^4x^3 = y^7$, &c.

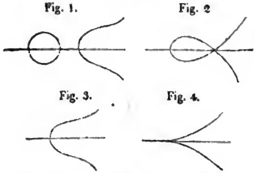
Cartesian PARABOLA, is a curve of the 2d order expressed by the equation, $xy = ax^3 + bx^2 + cx + d$, containing four infinite legs, viz, two hyperbolic ones, MM and Bm, to the common asymptote AE, tending contrary ways, and two parabolic legs MN and DN joining them, being Newton's 66th species of lines of the 3d order, and called by him a Trident. It is used by Descartes, in the 3d book of his Geometry, for finding the roots of equations of 6 dimensions, by means of its intersections with a circle. Its most simple equation is $xy = x^3 + g^3$. And points through which it is to pass may be easily found by means of a common parabola whose abscis is $ax^2 + bx + c$, and an hyperbola whose abscis is $\frac{d}{x}$; for y will be equal to the sum or difference of the corresponding ordinates of this parabola and hyperbola.



Descartes, in the place abovementioned, shows how to describe this curve by a continued motion. And Maclaurin does the same thing in a different way, in his Organica Geometria.

Diverging PARABOLA, is a name given by Newton to a species of five different lines of the third order, expressed by the equation $y^2 = ax^3 + bx^2 + cx + d$.

The first is a bell-form parabola, with an oval at its head (fig. 1); which is the case when the equation $0 = ax^3 + bx^2 + cx + d$, has three real and unequal roots; so that one of the most simple equations of a curve of this kind is $py^2 = x^3 + ax^2 + a^2x$.



The 2d is also a bell-form parabola, with a conjugate point, or infinitely small oval, at the head (fig. 1); being the case when the equation $0 = ax^3 + bx^2 + cx + d$ has its two less roots equal; the most simple equation of which is $py^2 = x^3 + ax^2$.

The 3d is a parabola, with two diverging legs, crossing one another like a knot (fig. 2); which happens when the equation $0 = ax^3 + bx^2 + cx + d$ has its two greater roots equal; the more simple equation being $py^2 = x^3 + ax^2$.

The 4th is a pure bell-form parabola (fig. 3); being the case when $0 = ax^3 + bx^2 + cx + d$ has two imaginary roots; and its most simple equation is $py^2 = x^3 + a^3$, or $py^2 = x^3 + a^2x$.

The 5th a parabola with two diverging legs, forming at their meeting a cusp or double point (fig. 4); being the case when the equation $0 = ax^3 + bx^2 + cx + d$ has three equal roots; so that $py^2 = x^3$ is the most simple equation of this curve, which indeed is the semi-cubical, or Neilian parabola.

If a solid generated by the rotation of a semi-cubical parabola, about its axis, be cut by a plane, each of these five parabolas will be exhibited by its sections. For, when the cutting plane is oblique to the axis, but falls below it, the section is a diverging parabola, with an oval at its head. When it is oblique to the axis, but passes through the vertex, the section is a diverging parabola, having an infinitely small oval at its head. When the cutting plane is oblique to the axis, it falls below it, and at the same time touches the curve surface of the solid, as well as cuts it, the section is a diverging parabola, with a nodus or knot. When the cutting plane falls above the vertex, either parallel or oblique to the axis, the section is a pure diverging parabola. And lastly, when the cutting plane passes through the axis, the section is the semi-cubical parabola from which the solid was generated.

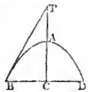
PARABOLIC *Asymptote*, is used for a parabolic line approaching to a curve, so that they never meet; yet by producing both indefinitely, their distance from each other becomes less than any given line.

There may be as many different kinds of these asymptotes as there are parabolas of different orders. When a curve has a common parabola for its asymptote, the ratio of the subtangent to the abscis approaches continually to the ratio of 2 to 1, when the axis of the parabola coincides with the base; but this ratio of the subtangent to the abscis approaches to that of 1 to 2, when the axis is perpendicular to the base. And by observing the limit to which the ratio of the subtangent and abscis approaches, parabolic asymptotes of various kinds may be discovered. See Maclaurin's Fluxions, art. 337.

PARABOLIC *Conoid*, is a solid generated by the rotation of a parabola about its axis.—This solid is equal to half its circumscribed cylinder; and therefore if the base be multiplied by the height, half the product will be the solid content.

To find the Curve Surface of a Paraboloid.

Let BAD be the generating parabola, AC = AT, and BT a tangent at B. Put $p = 3\cdot1416$, $y =$ BC, $x =$ AC = AT, and $t =$ BT $= \surd(4x^2 + y^2)$; then is the curve surface $= \frac{2}{3} ay \times (y + \frac{tt}{t+y})$.



See various other rules and geometrical constructions for the surfaces and solidities of parabolic conoids, in my Mensuration, part 3, sec. 6, 4th edition.

PARABOLIC *Pyramidoid*, is a solid figure thus named by Dr. Wallis, from its genesis, or formation, which is thus: Let all the squares of the ordinates of a parabola be conceived to be so placed, that the axis shall pass perpendicularly through all their centres; then the aggregate of all these planes will form the parabolic pyramidoid.—This figure is equal to half its circumscribed parallelopipedon. And therefore the solid content is found by multiplying the base by the altitude, and taking half the product; or the one of these by half the other.

PARABOLIC *Space*, is the space or area included by the curve line and base or double ordinate of the parabola. The area of this space, it has been shown under the article Parabola, is $\frac{2}{3}$ of its circumscribed parallelogram; which is its quadrature, and which was first found out by Archimedes, though some say by Pythagoras.

PARABOLIC *Spindle*, is a solid figure conceived to be formed by the rotation of a parabola about its base or double ordinate.—This solid is equal to $\frac{8}{15}$ of its circumscribed cylinder. See my Mensuration, prob. 15, pa. 296, &c, 4th edition.

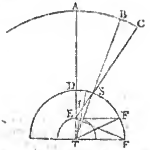
PARABOLIC *Spiral*. See HELICOID *Parabola*.

PARABOLIFORM *Curves*, a name sometimes given to the parabolas of the higher orders.

PARABOLOIDES, parabolas of the higher orders.—The equation for all curves of this kind being $a^{m-n}x^n = y^m$, the proportion of the area of any one, to the complement of it to the circumscribing parallelogram, will be as m to n.

PARACENTRIC *Motion*, denotes the space by which a revolving planet approaches nearer to, or recedes farther from, the sun, or centre of attraction.

Thus, if a planet in A move towards B; then is SB − SA = bB the paracentric motion of that planet: where S denotes the place of the sun.



PARACENTRIC *Solicitation of Gravity*, is the same as the Vis Centripeta; and is expressed by the line AL drawn from the point A, parallel to the ray SB (infinitely near SA), till it intersect the tangent BL.

PARACHUTE, or *Fall-breaker*, an instrument in form of a large umbrella, by means of which a person may safely descend to the ground with a small velocity, from a balloon, or from any great height in the air.—This is effected by the great resistance of the air against the descending machine; which, being resisted by a force increasing as the square of the velocity, soon comes to descend with a uniform motion. And, to determine what size it is necessary the parachute ought to have, in order that the velocity may be at any given moderate rate, see the solution of prob. 1, tract 38, vol. 3, of my Mathematical and Philosophical Tracts.

PARALLACTIC *Angle*, called also simply PARALLAX, is the angle EST (last fig. above) made at the centre of a star, &c, by two lines, drawn, the one from the centre of the earth at T, and the other from its surface at E.—Or, which amounts to the same thing, the parallactic angle is the difference of the two angles CEA and BTA, under which the real and apparent distances from the zenith are seen.—The sines of the parallactic angles ELT, EST, at the same or equal distances DS from the zenith, are in the reciprocal ratio of the distances, TL, and TS, from the centre of the earth.

PARALLAX, is an arch of the heavens intercepted between the true place of a star, and its apparent place. The true place of a star S, is that point of the heavens B, in which it would be seen by an eye placed in the centre of the earth at T. And the apparent place, is that point of the heavens C, where a star appears to an eye on the surface of the earth at E. This difference of places, is what is called absolutely the parallax, or the parallax of altitude; which Copernicus calls the commutation; and which therefore is an angle formed by two visual rays, drawn, the one from the centre, the other from the circumference of the earth, and traversing the body of the star; being measured by an arch of a great circle intercepted between the two points of true and apparent places, B and C.

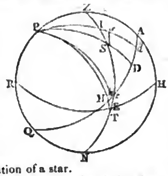
The PARALLAX *of Altitude* CB is properly the difference between the true distance from the zenith AB, and the apparent distance AC. Hence the parallax diminishes the altitude of a star, or increases its distance from the zenith; and it has therefore a contrary effect to the refraction.—The parallax is greatest in the horizon, called the horizontal parallax EFT. From hence it decreases all the way to the zenith D or A, where it is nothing; the real and apparent places there coinciding.

The horizontal parallax is the same, whether the star be in the true or apparent horizon.—The fixed stars have no sensible parallax, on account of their immense distance, to which the semidiameter of the earth is but a mere point: and therefore lines drawn from any two parts of the earth, to the stars, may be considered as parallel. Hence also, the nearer a star is to the earth, the greater is its parallax; and on the contrary, the farther it is off, the less is the parallax, at an equal elevation above the horizon. So the star at S has a less parallax than the star at I. Saturn is so high, that it is difficult to observe in him any parallax at all.

Parallax increases the right and oblique ascension, and diminishes the descension; it diminishes the northern declination and latitude in the eastern part, and increases them in the western; but it increases the southern declination in the eastern and western part; it diminishes the longitude in the western part, and increases it in the eastern. Parallax therefore has just opposite effects to refraction.

The doctrine of parallaxes is of the greatest importance in astronomy, for determining the distances of the planets, comets, and other phenomena of the heavens; for the calculation of eclipses, and for finding the longitude.

PARALLAX *of Right Ascension and Descension*, is an arch of the equinoctial Dd, by which the parallax of altitude increases the ascension, and diminishes the descension.



PARALLAX *of Declination*, is an arch of a circle of declination sI, by which the parallax of altitude increases or diminishes the declination of a star.

PARALLAX *of Latitude*, is an arch of a circle of latitude st, by which the parallax of altitude increases or diminishes the latitude.

Menstrual PARALLAX *of the Sun*, is an angle formed by two right lines; one drawn from the earth to the sun, and another from the sun to the moon, at either of their quadratures.

PARALLAX *of the Annual Orbit of the Earth*, is the difference between the heliocentric and geocentric place of a planet, or the angle at any planet, subtended by the distance between the earth and sun. There are various methods for finding the parallaxes of the celestial bodies; some of the principal and easier of which are as follow:

To observe the PARALLAX *of a Celestial Body.*—Observe when the body is in the same vertical with a fixed star which is near it, and in that position measure its apparent distance from the star. Observe again when the body and star are at equal altitudes from the horizon; and there measure their distance again. Then the difference of these distances will be the parallax very nearly.

To observe the Moon's PARALLAX.—Observe very accurately the moon's meridian altitude, and note the moment of time. To this time, equated, compute her true latitude and longitude, and from these find her declination; also from her declination, and the elevation of the equator, find her true meridian altitude. Subtract the refraction from the observed altitude: then the difference between the remainder and the true altitude, will be the parallax sought. If the observed altitude be not meridional, reduce it to the true altitude for the time of observation. By this means, in 1583, Oct. 12 day 5 h. 19 m. from the moon's meridian altitude observed at 13° 38′, Tycho found her parallax to be 54 minutes.

To observe the Moon's PARALLAX *in an Eclipse.*—In an eclipse of the moon observe when both horns are in the same vertical circle, and at that moment take the altitudes of both horns; then half their sum will be nearly the apparent altitude of the moon's centre; from which subtract the refraction, which gives the apparent altitude freed from refraction. But the true altitude is nearly equal to the altitude of the centre of the shadow at that time: now the altitude of the centre of the shadow is known, because we know the sun's place in the ecliptic, and his depression below the horizon, which is equal to the altitude of the opposite point of the ecliptic, in which the centre of the shadow is. Having thus the true and apparent altitudes, their difference is the parallax sought. Lahire makes the greatest horizontal parallax 1° 1′ 25″, and the least 54′ 5″. M. le Monnier determined the mean parallax of the moon to be 57′ 12″. Others have made it 57′ 18″.

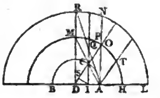
From the Moon's PARALLAX EST, *and altitude* SF (last fig. but one); *to find her distance from the Earth.*—From her apparent altitude given, there is given her apparent zenith distance, i. e. the angle AES; or by her true altitude, the complement angle ATS. Therefore, since at the same time, the parallactic angle S is known, the 3d or supplemental angle TES is also known. Then, considering the earth's semidiameter TE as 1, in the triangle TES are given all the angles and the side TE, to find ES the moon's distance from the surface of the earth, or TS her distance from the centre.

Thus Tycho, by the observation above mentioned, found the moon's distance at that time from the earth, was 62 of the earth's semidiameters. According to Lahire's determination, her distance when in the perigee is near 56 semidiameters, but in her apogee near $63\frac{1}{2}$; and therefore the mean nearly $59\frac{1}{4}$, or in round numbers 60 semidiameters.

Hence also, since, from the moon's theory, there is given the ratio of her distances from the earth in the several degrees of her anomaly; those distances being found, by the rule of three, in semidiameters of the earth, the parallax is thence determined to the several degrees of the true anomaly.

To observe the PARALLAX *of Mars.*—1. Suppose Mars to be in the meridian and equator at H: and that the observer, under the equator in A, observes him culminating with some fixed star. 2. If now the observer were in the centre of the earth, he would see Mars constantly in the same point of the heavens with the star; and therefore, together with it, in the plane of the horizon, or of the 6th horary: but since Mars here has some sensible parallax, and the fixed star has none, Mars will be seen in the horizon, when in P, the plane of the sensible horizon; and the star, when in R, the plane of the true horizon: therefore observe the time between the transit of Mars and of the star through the plane of the 6th hour.—3. Convert this time into minutes of the equator, at the rate of 15 degrees to the hour; by which means there will be obtained the arch PM, to which the angle PAM, and consequently the angle AMD, is nearly equal; which is the horizontal parallax of Mars.

If the observer be not under the equator, but in a parallel IQ, that difference will be a less arch QM; therefore, since the small arches QM and PM are nearly as their sines AD and ID; and since ADG



is equal to the distance of the place from the equator, i. e. to the elevation of the pole, or the latitude; therefore AD is to ID, as radius to the cosine of the latitude; hence we have this proportion, as the cosine of the latitude ID is to radius, so is the parallax observed in I, to the parallax under the equator.

Since Mars and the fixed star cannot be commodiously observed in the horizon; let them be observed in the circle of the 3d hour: and since the parallax observed there TO, is to the horizontal one PM, as IS to ID; say, as the sine of the angle IDS, or 45° (since the plane DO is in the middle between the meridian DH and the true horizon DM), is to radius, so is the parallax TO to the horizontal parallax PM.

If Mars be likewise out of the plane of the equator, the parallax found will be an arch of a parallel; which must therefore be reduced, as above, to an arch of the equator.—Lastly, if Mars be not stationary, but either direct or retrograde, by observations for several days find out what his motion is every hour, that his true place from the centre may be assigned for any given time.

By this method Cassini, who was the author of it, observed the greatest horizontal parallax of Mars to be 25"; but Mr. Flamsteed found it near 30". Cassini observed also the parallax of Venus by the same method.

To find the Sun's PARALLAX.—The great distance of the sun renders his parallax too small to fall under even the nicest immediate observation. Many attempts have indeed been made, both by the ancients and moderns, and many methods invented for that purpose. The first was that of Hipparchus, which was followed by Ptolemy, &c, and was founded on the observation of lunar eclipses. The second was that of Aristarchus, in which the angle subtended by the semidiameter of the moon's orbit, seen from the sun, was sought from the lunar phases. But these both proving deficient, astronomers now have recourse to the parallaxes of the nearer planets, Mars and Venus. Now from the theory of the motions of the earth and planets, there is known at any time the proportion of the distances of the sun and planets from us; and the horizontal parallaxes being reciprocally proportional to those distances; by knowing the parallax of a planet, that of the sun may be thence found.

Thus Mars, when opposite to the sun, is only half the distance of the sun from us, and therefore his parallax will be twice as great as that of the sun. And Venus, when in her inferior conjunction with the sun, is sometimes nearer us than he is; and therefore her parallax is greater in the same proportion. Thus, from the parallaxes of Mars and Venus, Cassini found the sun's parallax to be 10"; whence his distance comes out 22000 semidiameters of the earth.

But the most accurate method of determining the parallaxes of these planets, and thence the parallax of the sun, is that of observing their transit. However, Mercury, though frequently to be seen on the sun, is not fit for this purpose; because he is so near that luminary, that the difference of their parallaxes is always less than the solar parallax required. But the parallax of Venus, being almost 4 times as great as the solar parallax, will cause very sensible differences between the times in which she will seem to be passing over the sun at different parts of the earth. This method of determining the sun's parallax appears to have been first proposed by Mr. James Gregory, viz, in his Optica Promota, Schol. pa. 130, published in 1663.

With the view of engaging the attention of astronomers to this method of determining the sun's parallax, Dr. Halley communicated to the Royal Society, in 1691, a paper, containing an account of the several years in which such a transit may happen, computed from the tables which were then in use: those at the ascending node occur in the month of November O. S. in the years 918, 1161, 1396, 1631, 1639, 1874, 2109, 2117; and at the descending node in May O. S. in the years 1048, 1283, 1291, 1518, 1526, 1761, 1769, 1996, 2004. Philos. Trans. Abr. vol. 3, pa. 448, &c.

Dr. Halley even then concluded, that if the interval of time between the two interior contacts of Venus with the sun, could be measured to the exactness of a second, in two places properly situated, the sun's parallax might be determined within its 500th part. And this conclusion was more fully explained in a subsequent paper, concerning the transit of Venus in the year 1761, in the Philos. Trans. No. 348, or Abr. vol. 11, pa. 553.

It does not appear that any of the preceding transits had been observed; except that of 1639, by our ingenious countryman Mr. Horrox, and his friend Mr. Crabtree, of Manchester. But Mr. Horrox died on the 3d of January, 1641, at the age of 25, just after he had finished his treatise, Venus in Sole visa, in which he discovers a more accurate knowledge of the dimensions of the solar system, than his learned commentator Hevelius.

To give a general idea of this method of determining the horizontal parallax of Venus, and thence, by analogy, the parallax and distance of the sun, and of all the planets from him; let DBA be the earth, V Venus, and TSR the eastern limb of the sun. Now, to an observer at B, the point *t* of that limb will be on the meridian, and its place as referred to the heavens will be at E, and Venus will appear just within it at S. But to an observer at A, at the same instant, Venus is east of the sun, in the right line AVF; the point *t* of the sun's limb appears at *e* in the heavens, and if Venus were then visible she would appear at F. The angle CVA is the horizontal parallax of Venus; which is equal to the opposite angle FVE, measured by the arc FE. ASC is the sun's horizontal parallax, equal to the opposite angle *e*SE, measured by the arc *e*E; and FA*e* or VA*e* is Venus's horizontal parallax from the sun, which may be found by observing how much later in absolute time her total ingress on the sun, is, as seen from A, than as seen from B, which is the time she takes to move from V to *v*, in her orbit OVP.

If Venus were nearer the earth, as at U, her horizontal parallax from the sun would be the arc *fe*, which measures the angle FA*e*; and this angle is greater than the angle FA*e*, by the difference of their measures *ef*. So that, as the distance of the celestial object from the earth is less, its parallax is the greater.

Now it has been already observed, that the horizontal parallaxes of the planets are inversely as their distances from the earth's centre; and consequently, as the sun's distance at the time of the transit, is to Venus's distance, so is the parallax of Venus to that of the sun: and as the sun's mean distance from the earth's centre, is to his distance on the day of the transit, so is his horizontal parallax on that day, to his horizontal parallax at the time of his mean distance from the earth's centre. Hence his true distance in semidiameters of the earth may be obtained by the following analogy, viz, as the sine of the sun's parallax is to radius, so is unity or the earth's semidiameter, to the number of semidiameters of the earth in the sun's distance from the centre; which number multiplied by the number of miles in the earth's semidiameter, will give the number of miles in the sun's distance. Then from the proportional distances of the planets, determined by the theory of gravity, their true distances may be found. And from their apparent diameters at these known distances, their real diameters and bulks may be found.

Mr. Short, with great labour, deduced the quantity of the sun's parallax from the best observations that were made of the transit of Venus, on the 6th of June, 1761 (for which see Philos. Trans. vol. 51 and 52) both in Britain and in foreign parts, and found it to have been 8″·52 on the day of the transit, when the sun was very nearly at his greatest distance from the earth; and consequently 8″·65 when the sun is at his mean distance from the earth. See Philos. Trans. vol. 52, pa. 611, &c. Whence,

As sin. 8″·65	-	-	log. 5·6219140
to radius	-	-	10·0000000
So is 1 semidiameter	-	-	0·0000000
to 23822·84 semidiameters	-	-	4·3780860

that is, $23882\frac{84}{100}$ is the number of the earth's semidiameters contained in its distance from the sun; and this number of semidiameters being multiplied by 3985, the number of English miles contained in the earth's semidiameter (though later observations make this semidiameter only 395·7 miles), there is obtained 95,173,127 miles for the earth's mean distance from the sun. And hence, from the analogies under the article Distance, the mean distances of all the rest of the planets from the sun, in miles, are found as follow, viz,

Mercury's distance	-	-	36,841,468
Venus's distance	-	-	68,891,486
Mars's distance	-	-	145,014,148
Vesta's distance	-	-	224,145,086
Juno's distance	-	-	253,541,210
Pallas' distance	-	-	263,153,691
Ceres' distance	-	-	263,344,042
Jupiter's distance	-	-	494,990,976
Saturn's distance	-	-	907,956,130
Uranus' distance	-	-	1,816,074,574

In another paper (Philos. Trans. vol. 53, pa. 169), Mr. Short states the mean horizontal parallax of the sun at 8″·69. And Mr. Hornsby, from several observations of the transit of June 3, 1769 (for which see the Philos. Trans. vol. 59), deduces the sun's parallax for that day equal to 8″·65, and the mean parallax 8″·78; whence he makes the mean distance of the earth from the sun to be 93,726,900 English miles, and the distances of the other planets will be

Mercury's distance	-	-	36,281,700
Venus's distance	-	-	67,795,500
Mars's distance	-	-	142,818,000
Vesta's distance	-	-	220,739,053
Juno's distance	-	-	249,688,461
Pallas' distance	-	-	259,154,878
Ceres' distance	-	-	259,342,332
Jupiter's distance	-	-	487,472,000
Saturn's distance	-	-	894,162,000
Uranus' distance	-	-	1,788,477,960

See the Philos. Trans. vol. 61, pa. 572.

But others, by taking the results of those observations that are most to be depended on, have made the sun's parallax at his mean distance from the earth to be 8″·6045; and some make it only 8″·54. According to the former of these, the sun's mean distance from the earth is 95,109,736 miles; and according to the latter it is 95,834,742 miles. On the whole there seems reason to conclude that the sun's horizontal parallax may be stated at 8″·6, and his distance near 95 millions of miles. Hence, the following horizontal parallaxes:

Mean parallax of the sun	-	-	0′	8″·6
Moon's greatest	-	-	61	32
Moon's least	-	-	54	4
Moon's mean	-	-	57	48
Mars's	-	-	0	25

Of the Parallax *of the Fixed Stars.* As to the fixed stars, their distance is so great, that it has never been found that they have any sensible parallax, either with respect to the earth's diameter, or even with regard to the diameter of the earth's annual orbit round the sun, though this diameter is about 190 millions of miles. For, any of those stars being observed from opposite ends of this diameter, or at the interval of half a year between the observations, when the earth is in opposite points of her orbit, yet still the star appears in the same place and situation in the heavens, without any change that is sensible, or measurable with the very best instruments, not amounting to a single second of a degree. That is, the diameter of the earth's annual orbit, at the nearest of the fixed stars, does not subtend an angle of a single second; or, in comparison of the distance of the fixed stars, the extent of 190 millions of millions is but as a point!

The parallax of the fixed stars is a subject which has engaged the attention of many able astronomers, but hitherto their labours have been unsuccessful. Dr. Herschel, to whom astronomy is so much indebted for his ingenious labours and accurate observations, has proposed, in the Philosophical Transactions, a method for determining the annual parallax by means of double stars, by which it would become sensible, and might be ascertained at least to a greater degree of accuracy than could be effected by any other method, though it should not exceed the 10th part of a second. See Star. This problem is highly interesting, as it seems to offer the only rational data for determining the distances of the fixed stars; and if this could be ascertained with any tolerable degree of probability, it could not fail of being very gratifying to astronomers, and all those who contemplate with admiration the magnificent works of the Deity.

Parallax is also used, in Levelling, for the angle contained between the line of true level, and that of apparent level. And, in other branches of science, for the difference between the true and apparent places.

PARALLEL, in Geometry, is applied to lines, figures, and bodies, which are every-where equidistant from each other; or which, though infinitely produced, would never either approach nearer, or recede farther from, each other;

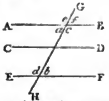
their distance being every-where measured by a perpendicular line between them. Hence,

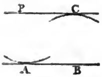
PARALLEL *right lines* are those which, though infinitely produced, would never meet: which is Euclid's definition of them.—Newton, in lemma 22, book 1, of his Principia, defines parallels to be such lines as tend to a point infinitely distant.—Parallel lines stand opposed to lines converging, and diverging.

Some define an inclining or converging line, to be that which will meet another at a finite distance, and a parallel line, that which will only meet at an infinite distance.

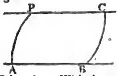
As a perpendicular is by some said to be the shortest of all lines that can be drawn to another; so a parallel is said to be the longest.

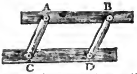
It is demonstrated by geometricians, that two lines, AB and CD, that are each parallel to one and the same right line EF, are also parallel to each other. And that if two parallel lines AB and EF be cut by any other line GH; then 1st, the alternate angles are equal; viz the angle $a = \angle b$, and $\angle c = \angle d$. 2d, The external angle is equal to the internal one on the same side of the cutting line; viz, the $\angle e = \angle d$, and the $\angle f = \angle b$. 3d, That the two internal angles on the same side are, taken together, equal to two right angles; viz, $\angle a + \angle d = 180°$, or $\angle c + \angle b = 180°$.





To draw a PARALLEL *Line*.—If the line to be parallel to AB must pass through a given point P: Take the nearest distance between the point P and the given line AB, by setting one foot of the compasses in P, and with the other describe an arc just to touch the line in A; then with that distance as a radius, and a centre B taken any where in the line, describe another arc C; lastly, through P draw a line PC to touch the arc C, and that will be the parallel sought.





Otherwise.—With the centre P, and a convenient radius, describe an arc BC, cutting the given line in B. Next, with the same radius, and centre B, describe another arc PA, cutting also the given line in A. Lastly, take AP between the compasses, and apply it from B to C; and through P and C draw the parallel PC required. Or, draw the line with the parallel ruler, described below, by laying one edge of the ruler along AB, and extending the other to the given point or distance. When the one line is to be at a given distance from the other; take that distance between the compasses as a radius, and with two centres, taken any where in the given line, describe two arcs; then lay a ruler just to touch the arcs, and by it draw the parallel.

PARALLEL *Planes*, are every-where equidistant, or have all the perpendiculars that are drawn between them, every-where equal.

PARALLEL *Rays*, in Optics, are those which keep always at an equal distance in respect to each other, from the visual object to the eye, from which the object is supposed to be infinitely distant.

PARALLEL *Ruler*, is a mathematical instrument, consisting of two equal rulers, AB and CD, either of wood or metal, connected together by two slender cross bars or blades AC and BD, moveable about the points or joints A, B, C, D.—There are other forms of this instrument, a little varied from the above; some having the two blades crossing in the middle, and fixed only at one end of them, the other two ends sliding in grooves along the two rulers; &c.

The use of this instrument is obvious. For the edge of one of the rulers being applied to any line, the other opened to any extent will be always parallel to the former; and consequently any parallels to this may be drawn by the edge of the ruler, opened to any extent.

PARALLEL *Sailing*, in Navigation, is the sailing on or under a parallel of latitude, or parallel to the equator.—Of this there are three cases.

1. Given the Distance and Difference of Longitude; to find the Latitude.—Rule. As the diff. of longitude is to the distance, so is radius to the cosine of the latitude. 2. Given the Lat. and Diff. of Longitude; to find the Distance.—Rule. As radius is to the cosine of the lat. so is the diff. of longitude to the distance. 3. Given the Latitude and Distance; to find the difference of longitude.—Rule. As the cosine of lat. is to radius, so is the distance to the diff. of longitude.

PARALLEL *Sphere*, is that situation of the sphere where the equator coincides with the horizon, and the poles with the zenith and nadir.—In this sphere, all the parallels of the equator become parallels of the horizon; consequently no stars ever rise or set, but all turn round in circles parallel to the horizon, as well as the sun himself, which when in the equinoctial wheels round the horizon the whole day. Also, After the sun rises to the elevated pole, he never sets for 6 months; and after his entering again on the other side of the line, he never rises for 6 months longer.

This position of the sphere can only happen to those who live at the poles of the earth, if any such there be. The greatest height the sun can rise to them, is 23½ degrees. They have but one day and one night, each being half a year long. See SPHERE.

PARALLELS, or *Places of Arms*, in a Siege, are deep trenches, 15 or 18 feet wide, joining the several attacks together; and serving to place the guard of the trenches in, to be at hand to support the workmen when attacked.—There are usually three in an attack: the first is about 600 yards from the covert-way, the second between 3 and 400, and the third near or on the glacis.—It is said they were first invented or used by Vauban.

PARALLELS *of Altitude*, or Almacantars, are circles parallel to the horizon, conceived to pass through every degree and minute of the meridian between the horizon and zenith; having their poles in the zenith.

PARALLELS, or PARALLEL *Circles*, called also Parallels of Latitude, and Circles of Lat. are lesser circles of the sphere, parallel to the equinoctial or equator.

PARALLELS *of Declination*, are lesser circles parallel to the equinoctial.

PARALLELS *of Latitude*, in Geography, are lesser circles parallel to the equator. But in Astronomy they are parallel to the ecliptic.

PARALLELISM, the quality of a parallel, or that which denominates it such. Or it is that by which two things, as lines, rays, or the like, become equidistant from each other.

Parallelism *of the Earth's Axis*, is that invariable situation of the axis, in the progress of the earth through the annual orbit, by which it always keeps parallel to itself; so that if a line be drawn parallel to its axis, while in any one position; the axis, in all other positions or parts of the orbit, will always be parallel to the same line.

In consequence of this parallelism, the axis of the earth points always, as to sense, to the same place or point in the heavens, viz, to the poles. Because, though really the axis, in the annual motion, describes the surface of a cylinder, whose base is the circle of the earth's annual orbit, yet this whole circle is but as a point in comparison with the distance of the fixed stars; and therefore all the sides of the cylinder seem to tend to the same point, which is the celestial pole.—To this parallelism is owing the change and variety of seasons, with the inequality of days and nights.

This parallelism is the necessary consequence of the earth's double motion; the one round the sun, the other round its own axis. Nor is there any necessity to imagine a third motion, as some have done, to account for this parallelism.

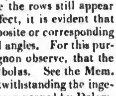
Parallelism *of Rows of Trees.* The eye placed at the end of an alley bounded by two rows of trees, planted in parallel lines, never sees them parallel, but always inclining to each other, towards the farther end.

Hence mathematicians have taken occasion to inquire, in what lines the trees must be disposed, to correct this effect of the perspective, and make the rows still appear parallel. And, to produce this effect, it is evident that the unequal intervals of any two opposite or corresponding trees may be seen under equal visual angles. For this purpose, M. Fabry, Tacquet, and Varignon observe, that the rows must be opposite semi-hyperbolas. See the Mem. Acad. Sciences, an. 1717. But notwithstanding the ingenuity of their speculations, it has been proved by Dalembert, and Bouguer, that to produce the effect proposed, the trees are to be ranged merely in two diverging right lines.

PARALLELOGRAM, in Geometry, is a quadrilateral right-lined figure, whose opposite sides are parallel to each other.—A parallelogram may be conceived as generated by the motion of a right line, along a plane, always parallel to itself.—Parallelograms have several particular denominations, and are of several species, according to certain particular circumstances, as follow:

When the angles of the parallelogram are right ones, it is called a rectangle.—When the angles are right, and all its sides equal, it is a square.—When the sides are equal, but the angles oblique ones, the figure is a rhombus or lozenge. And when both the sides and angles are unequal, it is a rhomboides. Every other quadrilateral whose opposite sides are neither parallel nor equal, is called a trapezium.

Properties of the Parallelogram.—1. In every parallelogram ABDC, the diagonal divides the figure into two equal triangles, ABD, ACD. Also the opposite angles and sides are equal, viz, the side AB = CD, and AC = BD, also the angle A = ∠ D, and the ∠ B = ∠ C. And



the sum of any two succeeding angles, or next the same side, is equal to two right angles, or 180 degrees, as ∠ A + ∠ C = ∠ C + ∠ D = ∠ D + ∠ B = ∠ B + ∠ A = two right-angles.

2. All parallelograms, as ABDC and *ab*DC, are equal, that are on the same base CD, and between the same parallels *ab*, CD; or that have either the same or equal bases and altitudes; and each is double a triangle of the same or equal base and altitude.

3. The areas of parallelograms are to one another in the compound ratio of their bases and altitudes. If their bases be equal, the areas are as their altitudes; and if the altitudes be equal, the areas are as the bases. And when the angles of the one parallelogram are equal to those of another, the areas are as the rectangles of the sides about the equal angles.

4. In every parallelogram, the sum of the squares of the two diagonals, is equal to the sum of the squares of all the four sides of the figure, viz,

$AD^2 + BC^2 = AB^2 + BD^2 + DC^2 + CA^2$. Also the two diagonals bisect each other; so that AE = ED, and BE = EC.

5. *To find the Area of a* Parallelogram.—Multiply any one side, as a base, by the height, or perpendicular let fall upon it from the opposite side. Or, multiply any two adjacent sides together, and the product by the sine of their contained angle, the radius being 1: viz,

The area is = CD × AP = AC × CD × sin. ∠ C.

Complement of a Parallelogram. See Complement.

Centre of Gravity of a Parallelogram. See Centre *of Gravity*, and Centrobaric *Method*.

Parallelogram, or Parallelism, or Pentagraph, also denotes a machine used for the ready and exact reduction or copying of designs, schemes, plans, prints, &c. in any proportion. See Pentagraph.

Parallelogram *of Forces*. See Forces, *Parallelogram of*.

Parallelogram *of the Hyperbola*, is the parallelogram formed by the two asymptotes of an hyperbola, and the parallels to them, drawn from any point of the curve. This term was first used by Huygens, at the end of his Dissertatio de Causa Gravitatis. This parallelogram, so formed, is of an invariable magnitude in the same hyperbola; and the rectangle of its sides is equal to the power of the hyperbola.

This parallelogram is also the modulus of the logarithmic system; and if it be taken as unity or 1, the hyperbolic sectors and segments will correspond to Napier's or the natural logarithms; for which reason these have been called the hyperbolic logarithms. If the parallelogram be taken = ·43429448190 &c, these sectors and segments will represent Briggs's logarithms; in which case the two asymptotes of the hyperbola make between them an angle of 25° 44′ 25″½.

Newtonian or Analytic Parallelogram, a term used for an invention of Sir Isaac Newton, to find the first term of an infinite converging series. It is sometimes called the Method of the Parallelogram and Ruler; because a ruler or right line is also used in it. This analytical parallelogram is formed by dividing any geometrical parallelogram into equal small squares or parallelograms, by lines drawn horizontally and perpendicularly through the equal divisions of the sides of the parallelogram. The small cells, thus formed, are filled with the dimensions or powers of the species *x* and *y*, and their products.

For instance, the powers of y, as y^0 or $1, y, y^2, y^3, y^4$, &c, being placed in the lowest horizontal range of cells; and the powers of x, as $x^0 = 1, x, x^2, x^3$, &c, in the vertical column to the left; or vice versa; these powers and their products will stand as in this figure:

A D

x^4	x^4y	x^4y^2	x^4y^3	x^4y^4
x^3	x^3y	x^3y^2	x^3y^3	x^3y^4
x^2	x^2y	x^2y^2	x^2y^3	x^2y^4
x	xy	xy^2	xy^3	xy^4
1	y	y^2	y^3	y^4

B C

Now when any literal equation is proposed, involving various powers of the two unknown quantities x and y, to find the value of one of these in an infinite series of the powers of the other; mark such of the cells as correspond to all its terms, or that contain the same powers and products of x and y; then let a ruler be applied to two, or perhaps more, of the parallelograms so marked, of which let one be the lowest in the left-hand column at AB, the other touching the ruler towards the right hand; and let all the rest, not touching the ruler, lie above it. Then select those terms of the equation which are represented by the cells that touch the ruler, and from them find the first term or quantity to be put in the quotient.

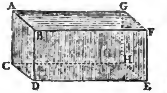
Of the application of this rule, Newton has given several examples in his Method of Fluxions and Infinite Series, pa. 9 and 10, but without demonstration; which has been supplied by others. See Colson's Comment on that treatise, pa. 192 et seq. Also Newton's Letter to Oldenburg, Oct. 24, 1676. Maclaurin's Algebra, pa. 251. And especially Cramer's Analyses des Lignes Courbes, pa. 148.—This author observes, that this invention, which is the true foundation of the method of series, was but imperfectly understood, and not valued as it deserved, for a long time. He thinks it however more convenient in practice to use the Analytical Triangle of the abbé de Gua, which takes in no more than the diagonal cells lying between A and C, and those which lie between them and B.

PARALLELOGRAM *Protractor*, a mathematical instrument, consisting of a semicircle of brass, with four rulers in form of a parallelogram, made to move to any angle. One of these rulers is an index, which shows on the semicircle the quantity of any inward and outward angle.

PARALLELOPIPED, or PARALLELOPIPEDON, is a solid figure contained under six parallelograms, the opposites of which are equal and parallel. Or, it is a prism whose base is a parallelogram.

Properties of the PARALLELOPIPEDON.—All parallelopipedons, whether right or oblique, that have their bases and altitudes equal, are equal; and each equal to triple a pyramid of an equal base and altitude.—A diagonal plane divides the parallelopipedon into two equal triangular prisms.—See other properties under the general term PRISM, of which this is only a particular species.

To measure the Surface and Solidity of a PARALLELOPIPEDON.—Find the areas of the three parallelograms AD, BE, and BG, which add into one sum; and double that sum will be the whole surface of the parallelopipedon. Or,



For the solidity; multiply the base by the altitude; that is, any one face or side by its distance from the opposite side; as AD × DE, or AB × BE, or BG × BD.

PARAMETER, a certain constant right line in each of the three conic sections; otherwise called also latus rectum.—This line is called parameter, or equal measurer, because it measures the conjugate axis by the same ratio which is between the two axes themselves; being indeed a third proportional to them; viz, a third proportional to the transverse and conjugate axes, in the ellipse and hyperbola; and, which is the same thing, a third proportional to any abscis and its ordinate in the parabola. So if t and c be the two axes in the ellipse and hyperbola, and x and y an abscis and its ordinate in the parabola;

then $t : c :: c : p = \frac{c^2}{t}$ the param. in the former,

and $x : y :: y : p = \frac{y^2}{x}$ the param. in the last.

The parameter is equal to the double ordinate drawn through the focus of any of the three conic sections.

PARAPET, or *Breastwork*, in Fortification, is a defence or screen, on the extreme edge of a rampart, or other work, serving to cover the soldiers and the cannon from the enemy's fire.—The thickness of the parapet is 18 or 20 feet, commonly lined with masonry; and 7 or 8 feet high, when the enemy has no command above the battery; otherwise, it should be raised higher, to cover the men while they load the guns. There are certain openings, called Embrasures, cut in the parapet, from the top downwards, to within about 2½ or 3 feet of the bottom of it, for the cannon to fire through; the solid pieces of it between one embrasure and another, being called Merlons.

PARAPET is also a little breast-wall, raised on the brinks of bridges, quays, or high buildings; to serve as a stay, and prevent people from falling over.

PARDIES (IGNATIUS GASTON), an ingenious French mathematician and philosopher, was born at Pau, in the province of Gascony, in 1636, his father being a counsellor of the parliament of that city.—At the age of 16 he entered into the order of Jesuits, and made so great a proficiency in his studies, that he taught polite literature, and composed many pieces in prose and verse with a distinguished delicacy of thought and style, before he was well arrived at the age of manhood. Propriety and elegance of language appear to have been his first pursuits; for which purpose he studied the Belles Lettres, and other learned productions. But afterwards he devoted himself to mathematical and philosophical studies, and read, with due attention, the most valuable authors, ancient and modern, in those sciences: so that, in a short time he made himself master of the Peripatetic and Cartesian philosophy, and taught them both with great reputation. Notwithstanding he embraced Cartesianism, yet he affected to be rather an inventor in philosophy himself. In this spirit he sometimes advanced very bold opinions, which met with opposers, who charged him with starting absurdities: but he was ingenious enough to give his notions a plausible turn, so as to clear them seemingly from contradictions. His reputation procured him a call to Paris, as professor of rhetoric in the college of Lewis the Great. He also taught the mathematics in that city, as he had before done in other places. He had from his youth a happy genius for that science, and made a great progress in it; and the glory which his writings acquired him, raised the highest expectations from his future labours; but these were all blasted by his early death, in 1673, at 37 years of age; falling a victim to his zeal, he having caught a contagious disorder by preaching to the prisoners in the Bicetre.

Pardies wrote with great neatness and elegance. His principal works are as follow :

1. Horologium Thaumaticum duplex ; 1662, in 4to.—2. Dissertatio de Motu et Natura Cometarum ; 1665, 8vo.—3. Discours du Mouvement Local ; 1670, 12mo.—4. Elemens de Geometrie ; 1670, 12mo.—This has been translated into several languages ; in English by Dr. Harris, in 1711.—5. Discours de la Connoissance des Bêtes ; 1672, 12mo.—6. Lettre d'un Philosophe à un Cartesien de ses amis ; 1672, 12mo.—7. La Statique ou la Science des Forces Mouvantes ; 1673, 12mo.—8. Description et Explication de deux Machines propres à faire des Cadrans avec une grande facilité ; 1673, 12mo.—9. Remarques du Mouvement de la Lumiere.—10. Globi Cœlestis in tabula plana redacti descriptio ; 1675, folio.

Part of his works were printed together, at the Hague, 1691, in 12mo ; and again at Lyons, 1725.—Pardies had a dispute also with Sir Isaac Newton, about his new theory of light and colours, in 1672. His Letters are inserted in the Philosophical Transactions for that year.

PARENT (Anthony), a respectable French mathematician, was born at Paris in 1666. He showed an early propensity to the mathematics, eagerly perusing such books in that science as fell in his way. His custom was to write remarks in the margins of the books he read ; and in this way he had filled a number of books with a kind of commentary by the time he was 13 years of age ; and not many years after a treatise on gnomonics, and another on geometry.

His friends then sent for him to Paris to study the law ; and in obedience to them he went through a course in that faculty : which was no sooner finished than, urged by his passion for mathematics, he shut himself up in the college of Dormans, that no avocation might take him from his beloved study : and, with an allowance of less than 200 livres a-year, he lived content in this retreat, from which he never stirred but to the Royal College, to hear the lectures of M. Lahire or M. de Sauveur ; adding to his small income by teaching some pupils. M. Parent made two campaigns with the marquis d'Aligre, by which he instructed himself sufficiently in viewing fortified places ; of which he drew a number of plans, though he had never learned the art of drawing.

From this period he spent his time in a continual application to the study of natural philosophy, and mathematics in all its branches, both speculative and practical ; to which he also added anatomy, botany, and chemistry ; his genius and indefatigable application overcoming every obstacle to these pursuits.

M. de Billettes being admitted into the Academy of Sciences at Paris in 1699, with the title of their mechanician, he named M. Parent for his elève or disciple, a branch of mathematics in which he chiefly excelled. It was soon discovered in this society, that he engaged in all the different subjects which were brought before them ; and indeed that he had a hand in every thing. In his productions he was charged with obscurity ; a fault for which he was indeed justly blamed.

By a regulation of the academy in 1716, the class of elèves was suppressed, as that distinction seemed to put too great an inequality between the members. M. Parent was made an adjunct or assistant member for the class of geometry : though he enjoyed this promotion but a very short time ; being cut off by the small-pox the same year, at 50 years of age.

M. Parent, besides leaving many pieces in manuscript, published the following works :

1. Elemens de Mecanique et de Physique, 12mo, 1700.
2. Recherches de Mathematiques et de Physique ; 3 vols 4to, 1714.
3. Arithmetique theorico-pratique ; in 8vo, 1714.
4. A great many papers in the volumes of the Memoirs of the Academy of Sciences, from the year 1700 to 1714, several papers in almost every volume, on a variety of branches in the mathematics.

PARGETING, in Building, is used for the plastering of walls ; sometimes for plaster itself.

PARHELION, or Parhelium, denotes a mock-sun, or meteor, appearing as a very bright light by the side of the sun ; being formed by the reflection of his beams in a cloud properly situated.

Parhelia usually accompany the coronæ, or luminous circles, and are placed in the same circumference, and at the same height. Their colours resemble those of the rainbow ; the red and yellow are on that side towards the sun, and the blue and violet on the other. Though coronæ are sometimes seen entire, without any parhelia ; and sometimes parhelia without coronæ.

The apparent size of parhelia is the same as that of the true sun ; but they are not always round, nor so bright as the sun ; and when several appear, some are brighter than others. They are tinged externally with colours like the rainbow, and many of them have a long fiery tail opposite to the sun, but paler towards the extremity. Some parhelia have been observed with two tails and others with three. These tails mostly appear in a white horizontal circle, commonly passing through all the parhelia, and would go through the centre of the sun if it were entire. Sometimes there are arcs of lesser circles, concentric to this, touching those coloured circles which surround the sun : these are also tinged with colours, and contain other parhelia.

Parhelia are generally situated in the intersections of circles ; but Cassini says, those which he saw in 1683, were on the outside of the coloured circle, though the tails were in the circle that was parallel to the horizon. M. Aepinus apprehends, that parhelia with elliptical coronæ are more frequent in the northern regions, and those with circular ones in the southern. They have been visible for one, two, three, or four hours together ; and it is said that in North America they continue several days, and are visible from sun-rise to sun-set. When the parhelia disappear, it sometimes rains, or there falls snow in the form of oblong spiculæ. And Mariotte accounts for the appearance of parhelia from an infinity of small particles of ice floating in the air, which multiply the image of the sun, either by refracting or breaking his rays, and thus making him appear where he is not ; or by reflecting them, and serving as mirrors.

Many philosophers have written on parhelia ; as Aristotle, Pliny, Scheiner, Gassendi, Descartes, Huygens, Hevelius, Lahire, Cassini, Grey, Halley, Maraldi, Musschenbroek, &c. See Smith's Optics, book 1, chap. 11 ; Priestley's Hist. of Light, &c, pa. 613 ; Musschenbroek's Introduction, &c, vol. 2, pa. 1038, 4to ; and Dr. Thomas Young's Philosophy.

PARODICAL *Degrees*, in an equation, a term that has been sometimes used to denote the several regular terms, or lower powers of the unknown quantity x, in an equation, when the indices of the powers ascend or descend orderly in an arithmetical progression. Thus $x^3 + mx^2 + nx = p$ is a cubic equation where no term is wanting, but having all its parodic degrees; the indices of the terms regularly descending thus, 3, 2, 1, 0.

PART, *Aliquant*, *Aliquot*, *Circular*, *Proportional*, *Similar*, &c. See the respective adjectives.

PARTICLE, the minute part of a body, or an assemblage of several of the atoms of which natural bodies are composed. Particle is sometimes considered as synonymous with atom, and corpuscle; and sometimes they are distinguished. Particles are, as it were, the elements of bodies; by the various arrangement and texture of which, with the difference of the cohesion, &c, are constituted the several kinds of bodies, hard, soft, liquid, dry, heavy, light, &c. The smallest particles or corpuscles cohere with the strongest attractions, and always compose larger particles of weaker cohesion: and many of these, cohering, compose still larger particles, whose vigour is still weaker; and so on for divers successions, till the progression end in the largest particles, upon which the operations in chemistry, and the colours of natural bodies, depend; and which, by cohering, compose bodies of sensible magnitude.

PARTY *Arches*, in Architecture, are arches built between separate tenures, where the property is intermixed, and apartments over each other do not belong to the same estate.

PARTY *Walls*, are partitions of brick made between buildings in separate occupations, for preventing the spread of fire. These are made thicker than the external walls; and their thickness in London is regulated by act of parliament of the 14th of George the Third.

PASCAL (BLAISE), a respectable French mathematician and philosopher. He was born at Clermont, in Auvergne, in the year 1623. His father, Stephen Pascal, was president of the Court of Aids in his province: he was also a very learned man, an able mathematician, and a friend of Descartes. Having an extraordinary tenderness for this child, his only son, he quitted his office in his province, and settled at Paris in 1631, that he might be quite at leisure to attend his son's education, which he conducted himself, and young Pascal never had any other master.

From his infancy Blaise gave proofs of a very extraordinary capacity. He was extremely inquisitive; desiring to know the reason of every thing; and when good reasons were not given him, he would seek for better; nor would he ever yield his assent but on such as appeared to him well grounded. What is told of his manner of learning the mathematics, as well as the progress he quickly made in that science, seems almost miraculous. From a simple mathematical definition, he discovered by degrees, and by the unaided force of his mind, that the three angles of every triangle are together equal to two right angles, as well as several of the other theorems of Euclid. At 16 years of age Pascal composed a tract on the Conic Sections, which was considered as a prodigy of sagacity. Scarcely had he attained his 19th year, when he invented the famous arithmetical machine which bears his name, and by which all kinds of operations in numbers may be performed, by the use of the eyes and hands only. Soon afterwards his experiments decided the opinions of philosophers respecting the weight of the air. He invented the arithmetical triangle, and the elements of the arithmetic of probabilities.

All these labours ruined the health of Pascal. Bodily weakness obliged him to suspend all mental exertions, and to commence a course of moderate exercise. One day in 1654, as he was riding to the bridge of Neuilly, in a chariot-and-four, the two foremost horses ran away close to a precipice, where there was no parapet, down which they rushed into the Seine. Fortunately they broke the traces by their first effort, and left the chariot standing on the very brink of the precipice. This accident so much disturbed the brain of Pascal, that ever after he imagined there was an abyss on his left hand. He afterwards wholly renounced the world, and retired to the abbey of Port-Royal, where the regular life which he led, procured him very long intervals of health, during which he wrote the celebrated Provincial Letters, one of the most perfect works in the French language. For many years Pascal relinquished all purely human sciences. But having been tormented by a most severe tooth-ache, which almost wholly deprived him of rest, he sought by intense application the means of mitigating his pain; and the discoveries which he then made on the cycloidal curve are, even at the present day, reckoned among the greatest efforts of the human mind. The first idea of that remarkable curve seemed to have occurred to Galileo, and several other mathematicians had successively developed its properties. Pascal, having attentively considered that curve, wished to make a trial of the talents of his cotemporary geometricians. With this view he proposed to them some new problems on the cycloid, promising 40 pistoles to the first person, and 20 to the second, who should solve these problems. The only person who returned answers to all the problems, and claimed the prizes, were Dr. Wallis and father Laloubere the Jesuit. Huygens squared the segment comprehended between the vertex of the cycloid and that of the diameter of the generating circle. Slusius measured the arc of that curve in a very elegant manner; and Wren found its rectification. But all these researches did not entirely answer the questions in the programma circulated by Pascal, under the name of A. Detonville. He affirmed that Wallis and Laloubere were mistaken in several particulars, and therefore he withheld the promised rewards. He himself however gave perfect solutions of all the problems which he had proposed, and of several others, which were necessary to complete the theory of the cycloid. After languishing for several years in a very imbecile state of body and mind, M. Pascal died at Paris the 19th of August 1662, at 39 years of age.

Towards the close of his life, he employed himself wholly in devout and moral reflections, writing down those which he deemed worthy of being preserved. The first bit of paper he could find was employed for this purpose; and he commonly set down only a few words of each sentence, as he wrote them merely for his own use. The scraps of paper on which he had written these thoughts, were found after his death filed upon different pieces of string, without any order or connection; and being copied exactly as they were written, they were afterwards arranged and published, under the title of Pensées, &c, or Thoughts upon Religion and other Subjects; being parts of a work he had intended against atheists and infidels, which has been much admired. After his death appeared also two other little tracts; the one entitled, The Equilibrium of Fluids; and the other, The Weight of the Mass of Air. The works of Pascal were collected in 5 volumes, 8vo, and published at the Hague, and at Paris, in 1779. This edition of Pascal's works may be considered as the first published; at least the greater part of them were not before collected into one body, and some of them had remained only in manuscript. For this collection, the public were indebted to the abbé Bossu, and Pascal was deserving of such an editor.

PATE, in Fortification, a kind of platform, like what is called a horse-shoe; not always regular, but commonly oval, encompassed only with a parapet, and having nothing to flank it. It is usually erected in marshy grounds, to cover a gate of a town, or the like.

PATH *of the Vertex*, a term frequently used by Mr. Flamsteed, in his Doctrine of the Sphere, denoting a circle, described by any point of the earth's surface, as the earth turns round its axis. This point is considered as vertical to the earth's centre; and is the same with what is called the vertex or zenith in the Ptolemaic projection. The semidiameter of this path of the vertex, is always equal to the complement of the latitude of the point or place that describes it; that is, to the place's distance from the pole of the world.

PAVILION, in Architecture, is a kind of turret, or building usually insulated, and contained under a single roof; sometimes square and sometimes in form of a dome: thus called from the resemblance of its roof to a tent.

PAVO, *Peacock*, a new constellation, in the southern hemisphere, added by the modern astronomers. It contains 14 stars.

PAUSE, or Rest, in Music, a character of silence and rest; called also by some a mute figure; because it shows that some part or person is to be silent, while the others continue the song.

PECK, a measure or vessel used in measuring grain, pulse, and the like dry substances. It contains 2 gallons, or the 4th part of a bushel.

PEDESTAL, in Architecture, the lowest part of an order of columns; being that which sustains the column, and serves it as a foot to stand upon. It is a square body or die, with a cornice and base. The proportions and ornaments of the pedestal are different in the different orders. Vignola indeed, and most of the moderns, make the pedestal, and its ornaments, in all the orders, one third of the height of the column, including the base and capital. But some deviate from this rule.

Perrault makes the proportions of the three constituent parts of pedestals, the same in all the orders; viz, the base one fourth of the pedestal; the cornice an eighth part; and the socle or plinth of the base, two thirds of the base itself. The height of the die is what remains of the whole height of the pedestal.

The *Tuscan* Pedestal is the simplest and lowest of all; from 3 to 5 modules high. It has only a plinth for its base, and an astragal crowned for its cornice.

The *Doric* Pedestal is made 4 or 5 modules in height, by the moderns; for no ancient columns, of this order, are found with any pedestal, or even with any base.

The *Ionic* Pedestal is from 5 to 7 modules high.

The *Corinthian* Pedestal is the richest and most delicate of all, and is from 4 to 7 modules high.

The *Composite* Pedestal is of 6 or 7 modules in height.

Square Pedestal has its breadth and height equal.

Double Pedestal, is that which supports two columns, being broader than it is high.

Continued Pedestal, is that which supports a row of columns without any break or interruption.

Pedestals *of Statues*, are those serving to support figures or statues.

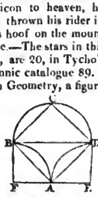
PEDIMENT, in Architecture, a kind of low pinnacle; serving to crown porticos, or finish a frontispiece; and placed as an ornament over gates, doors, windows, niches, altars, &c; being usually of a triangular form, but sometimes an arch of a circle. Its height is various, but it is thought most beautiful when the height is one fifth of the length of its base.

PEDOMETER, or Podometer, foot-measurer, or way-wiser; a mechanical instrument, in form of a watch, and consisting of various wheels and teeth; which, by means of a chain, or string, fastened to a man's foot, or to the wheel of a chariot, advance a notch each step, or each revolution of the wheel: by which it numbers the paces or revolutions, and so the distance from one place to another.

Pedometer is also sometimes used for the common surveying wheel, an instrument chiefly used in measuring roads; popularly called the way-wiser. See Perambulator.

PEGASUS, the Horse, a constellation of the northern hemisphere, figured in the form of a flying horse; being one of the 48 ancient constellations. It is fabled, by the Greeks, to have been the offspring of an amour between Neptune and the Gorgon Medusa; and to have been that on which Bellerophon rode when he overcame the Chimera; and that flying from mount Helicon to heaven, he there became a constellation; having thrown his rider in the flight; and that the stroke of his hoof on the mount opened the sacred fountain Hippocrene.—The stars in this constellation, in Ptolemy's catalogue, are 20, in Tycho's 19, in Hevelius's 38, and in the Britannic catalogue 89.

PELECOIDES, or *Hatchet-form*, in Geometry, a figure in form of a hatchet. As the figure ABCDA, contained under the semicircle BCD and the two quadrantal arcs AB and AD. The area of the pelecoides is equal to the square AC, and this again is equal to the rectangle BE. It is equal to the square, because the two segments AB and AD, which it wants of the square on the lower part, are compensated by the two equal segments BC and CD, by which it exceeds on the upper part. And the square is equal to the rectangle BE, because the triangle ABD, which is half the square, is also half the rectangle BE of the same base and height with it.



PELL (Dr. John), an eminent English mathematician, descended from an ancient family in Lincolnshire, was born at Southwick in Sussex, March 1, 1610, where his father was minister. He received his grammar education at the free-school at Stenning in that county. At the age of 13 he was sent to Trinity-college in Cambridge, though at that time as good a scholar as most masters of arts in that university; but though he was eminently skilled in the Greek and Hebrew languages, he never offered himself a candidate at the election of scholars or fellows of his college.

In 1629 he drew up the "Description and Use of the Quadrant, written for the Use of a Friend," in two books; the original manuscript of which is still extant among his papers in the Royal Society. And the same year he held a correspondence with Mr. Briggs on the subject of logarithms.

In 1630 he wrote, "Modus supputandi Ephemerides Astronomicas, &c, ad an. 1630 accommodatus;" and, "A Key to unlock the meaning of Johnnnes Trithemius, in his Discourse of Steganography," which Key he imparted to Mr. Samuel Hartlib and Mr. Jacob Homedæ. The same year he took the degree of master of arts at Cambridge. And the year following he was incorporated in the university of Oxford. June the 7th, he wrote "A Letter to Mr. Edmund Wingate, on Logarithms," and Oct. 5, 1631, "Commentationes in Cosmographiam Alstedii."

March 6, 1634, he finished his "Astronomical History of Observations of Heavenly Motions and Appearances;" and April the 10th, his "Ecliptica Prognostica, or Foreknower of the Eclipses, &c."—In 1634 he translated "The Everlasting Tables of Heavenly Motions," grounded on the Observations of all Times, and agreeing with them all, by Philip Lansberg, of Ghent in Flanders. And June the 12th, the same year, he committed to writing, "The Manner of deducing his Astronomical Tables out of the Tables and Axioms of Philip Lansberg."—March the 9th, 1635, he wrote "A Letter of Remarks on Gellibrand's Mathematical Discourse on the Variation of the Magnetic Needle." And the 3d of June following, another on the same subject.

His eminence in mathematical knowledge was now so great, that he was thought worthy of a professor's chair in that science; and, on the vacancy of one at Amsterdam in 1639, Sir William Boswell, the English resident with the States-General, used his interest, that he might succeed in that professorship: it was not filled however till 1643, when Pell was chosen to it; and he read with great applause public lectures on Diophantus.—In 1644 he printed at Amsterdam, in two pages 4to, "A Refutation of Longomontanus's Discourse, De Vera Circuli Mensura."

In 1646, on the invitation of the Prince of Orange, he removed to the new college at Breda, as professor of mathematics, with a salary of 1000 guilders a year.—His "Idea Matheseos," which he had addressed to Mr. Hartlib, who in 1639 had sent it to Descartes and Mersenne, was printed 1650 at London, in 12mo, in English, with the title of "An Idea of Mathematics," at the end of Mr. John Durie's Reformed Library-keeper. It is also printed by Mr. Hooke, in his Philosophical Collections, No. 5, pa. 127; and is esteemed our author's principal work.

In 1652 Pell returned to England: and in 1654 he was sent by the protector Cromwell agent to the protestant cantons in Switzerland; where he continued till June 23, 1658, when he set out for England, where he arrived about the time of Cromwell's death. His negociations abroad gave afterwards a general satisfaction, as it appeared he had done no small service to the interest of king Charles the 2d, and of the church of England; so that he was encouraged to enter into holy orders; and in the year 1661 he was instituted to the rectory of Fobbing in Essex, given him by the king. In December that year he brought into the upper house of convocation the calendar reformed by him, assisted by Sancroft, afterwards archbishop of Canterbury.—In 1673 he was presented by Sheldon, bishop of London, to the rectory of Laingdon in Essex; and, on the promotion of that bishop to the see of Canterbury soon after, became one of his domestic chaplains. He was then doctor of divinity, and expected to be made a dean; but he attended so much to his improvement in the philosophical and mathematical sciences that he lost sight of his private advantage. The truth is, he was a helpless man, as to worldly affairs, and his tenants and relations imposed on him, cozened him of the profits of his parsonage, and kept him so indigent, that he wanted necessaries, even ink and paper, to his dying day. He was for some time confined to the King's-bench prison for debt; but, in March 1682, was invited by Dr. Whitler to live in the college of physicians. Here he continued till June following; when he was obliged, by his ill state of health, to remove to the house of a grandchild of his in St. Margaret's Church-yard, Westminster. But he died at the house of Mr. Cothorne, reader of the church of St. Giles's in the Fields, December the 12th, 1685, in the 74th year of his age, and was interred at the expense of Dr. Busby, master of Westminster-school, and Mr. Sharp, rector of St. Giles's, in the rector's vault under that church.—Dr. Pell published some other things not yet mentioned, a list of which is as follows: viz,

1. An Exercitation concerning Easter; 1644, in 4to.
2. A Table of 10,000 square numbers, &c; 1672, folio.
3. An Inaugural Oration at his entering on the Professorship at Breda.
4. He made great alterations and additions to Rhonius's Algebra, printed at London 1668, 4to, under the title of, An Introduction to Algebra; translated out of the High Dutch into English by Thomas Branker, much altered and augmented by D. P. (Dr. Pell.) Also a Table of Odd Numbers, less than 100,000, showing those that are incomposite, &c, supputated by the same Thomas Branker. See this table under the article Prime *Numbers*.
5. His Controversy with Longomontanus concerning the Quadrature of the Circle; Amsterdam, 1646, 4to.

He also wrote a Demonstration of the 2d and 10th books of Euclid; which piece was in MS. in the library of lord Brereton in Cheshire: as also Archimedes's Arenarius, and the greatest part of Diophantus's 6 books of Arithmetic; of which author he was preparing a new edition, in which he intended to have corrected the translation, and made new illustrations. He designed also to publish an edition of Apollonius, but laid it aside, in May 1645, at the desire of Golius, who was engaged in an edition of that author from an Arabic manuscript given him at Aleppo 18 years before. Letters of Dr. Pell to Sir Charles Cavendish, in the Royal Society.

Some of his manuscripts he left at Brereton in Cheshire, where he resided some years, being the seat of William lord Brereton, who had been his pupil at Breda. A great many others came into the hands of Dr. Busby; which Mr. Hooke was desired to use his endeavours to obtain for the Royal Society. But they continued buried under dust, and mixed with the papers and pamphlets of Dr. Busby, in 4 large boxes, till 1755; when Dr. Birch, secretary to the Royal Society, procured them for that body, from the trustees of Dr. Busby. The collection contains not only Pell's mathematical papers, letters to him, and copies of those from him, &c, but also several manuscripts of Walter Warner, the mathematician and philosopher, who lived in the reigns of James the First and Charles the First.

Dr. Pell invented the method of ranging the several steps of an algebraical calculus, in a proper order, in so many distinct lines, with the number affixed to each step, and a short description of the operation or process in the line. He also invented the character $\div$ for division, ⊕ for involution, and ⧢ for evolution.

He was also the first who discovered the method of solving the equation $ax^2 - y^2 = 1$, being the same as that given by Euler in the second volume of his algebra. This problem was proposed by Fermat as a challenge to all the English mathematicians, though it is probable (as he never gave a solution to it himself) that he was unacquainted with the true mode of operation at the time he proposed it.

PEMBERTON (HENRY), M. D. & F. R. S. born at London in 1694, was a learned physician and mathematician; as well as an expert mechanist, readily performing with his own hand several mechanical operations. After studying grammar at a school, and the higher classics under Mr. John Ward, afterwards professor of rhetoric at Gresham-college, he went to Leyden, to attend the lectures of the celebrated Boerhaave, to qualify himself for the profession of medicine. Here also, as well as in England, he constantly mixed, with his professional studies, those of the best mathematical authors, whom he contemplated with great effect. From hence he went to Paris, to perfect himself in the practice of anatomy, to which he readily attained, being naturally dextrous in all manual operations. Having obtained his main object, he returned to London, enriched also with other branches of scientific knowledge, and a choice collection of mathematical books, both ancient and modern, from the sale of the valuable library of the abbé Gallois, which took place during his stay in Paris. After his return he assiduously attended St. Thomas's Hospital, to acquire the London practice of physic, though he seldom afterwards practised, owing to his delicate state of health. In 1719 he returned to Leyden, to take his degree of M. D. where he was kindly entertained by his friend Dr. Boerhaave. After his return to London, he became more intimately acquainted with Dr. Mead, Sir I. Newton, and other eminent men, with whom he afterwards cultivated the most friendly connexions. Hence he was useful in assisting Sir I. Newton in preparing a new edition of his Principia, in writing an account of his philosophical discoveries, in bringing forward Mr. Robins, and writing some pieces printed in the 2d volume of that gentleman's collection of tracts, in Dr. Mead's Treatise on the Plague, and in his edition of Cowper on the Muscles, &c. Being chosen professor of physic in Gresham-college, he undertook to give a course of lectures on chemistry, which was improved every time he exhibited it, and was published in 1771, by his friend Dr. James Wilson. In this situation too, at the request of the college of physicians, he revised and reformed their Pharmacopœia, in a new and much improved edition. After a long and laborious life spent in improving science, and assisting its cultivators, Dr. Pemberton died in 1771, at 77 years of age.

Besides the doctor's writings above-mentioned, he wrote numerous other pieces; as, 1. Epistola ad Amicum de Cotesii inventis; demonstrating Cotes's celebrated theorem, and showing how his theorems by ratios and logarithms may be done by the circle and hyperbola.—2. Observations on Poetry, especially the Epic, occasioned by Glover's Leonidas.—3. A Plan of a Free State, with a King at the Head; not published.—4. Account of the Ancient Ode; printed in the preface to West's Pindar.—5. On the Dispute about Fluxions, in the 2d vol. of Robins's works.—6. On the Alteration of the Style and Calendar.—7. On reducing the Weights and Measures to one Standard.—8. A Dissertation on Eclipses.—9. On the Loci Plani, &c. His numerous communications to the Royal Society, on a variety of interesting subjects, extend from the 32d to the 62d vol. of the Philos. Trans.

After his death many valuable pieces were found among his papers, viz. A short History of Trigonometry, from Menelaus to Napier. A comment on an English Translation of Newton's Principia. Demonstrations of the Spherics and spherical Projections, enough to compose a treatise on those subjects. A Dissertation on Archimedes's Screw. Improvements in Guaging. In a given latitude, to find the point of the ecliptic that ascends the slowest. To find when the oblique ascension differs most from the arch to which it belongs. On the principles of Mercator's and middle-latitude sailing. To find the heliacal rising of a star. To compute the moon's parallax. To determine the course of a comet in a parabolic orbit. And others, all neatly performed. On the whole, Dr. Pemberton appears to have been a clear and industrious author, but his writings are too diffuse and laboured.

PENCIL *of Rays*, in Optics, is a double cone, or pyramid of rays, joined together at the base; as BGSC: the one cone having its vertex in some point of the object at B, and the crystalline humour, or the glass GLS for its base; and the other having its base on the same glass, or crystalline, but its vertex in the point of convergence, as at C.

PENDULUM, in Mechanics, any heavy body, so suspended as that it may swing backwards and forwards, about some fixed point, by the force of gravity. These alternate ascents and descents of the pendulum, are called its oscillations, or vibrations; each complete oscillation being the descent from the highest point on one side, down to the lowest point of the arch, and so on up to the highest point on the other side. The point round which the pendulum moves, or vibrates, is called its centre of motion, or point of suspension; and a right line drawn through the centre of motion, parallel to the horizon, and perpendicular to the plane in which the pendulum moves, is called the axis of oscillation. There is also a certain point within every pendulum, into which, if all the matter that composes the pendulum were collected, or condensed as into a point, the times in which the vibrations would be performed, would not be altered by such condensation; and this point is called centre of oscillation. The length of the pendulum is always estimated by the distance of this point below the centre of motion; being usually near the bottom of the pendulum; but in a cylinder, or any other uniform prism or rod, it is at the distance of one third from the bottom, or two-thirds from and below the centre of motion.

The length of a pendulum, so measured to its centre of oscillation, that it will perform each vibration in a second of time, thence called the seconds pendulum, has, in the latitude of London, been generally taken at $39\frac{2}{10}$ or $39\frac{1}{5}$ inches; but by some very ingenious and accurate experiments, the late celebrated Mr. George Graham found the true length to be $39\frac{128}{1000}$, inches, or $39\frac{1}{8}$ inches very nearly.

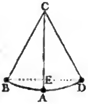
The length of the pendulum vibrating seconds at Paris, was found by Varin, Deshays, Deglos, and Godin, to be

$440\frac{5}{9}$ lines; by Picard $440\frac{1}{2}$ lines; and by Mairan $440\frac{17}{30}$ lines.

Galileo was the first who made use of a heavy body annexed to a thread, and suspended by it, for measuring time, in his experiments and observations. But according to Sturmius, it was Riccioli who first observed the isochronism of pendulums, and made use of them in measuring time. After him, Tycho, Langrene, Wendeline, Mersenne, Kircher, and others, observed the same thing; though, it is said, without any intimation of what had been done by Riccioli. But it was the celebrated Huygens who first demonstrated the principles and properties of pendulums, and probably the first who applied them to clocks. He demonstrated, that if the centre of motion were perfectly fixed and immoveable, and all manner of friction, and resistance of the air, &c, removed, that a pendulum, once set in motion, would for ever continue to vibrate without any decrease of motion, and that all its vibrations would be perfectly isochronal, or performed in the same time, the arc of vibration remaining constant. Hence the pendulum has universally been considered as the best chronometer or measurer of time. And as all pendulums of the same length perform their vibrations in the same time, the arc of vibration being the same, without regard to their different weights, it has been suggested, by means of them, to establish an universal standard for all countries. On this principle Mouton, canon of Lyons, has a treatise, De Mensura posteris transmittenda; and several others since, as Whitehurst, &c. See *Universal* MEASURE.

Pendulums are either simple or compound, and each of these may be considered either in theory, or as in practical mechanics among artisans.

A Simple PENDULUM, in Theory, consists of a single weight, as A, considered as a point, and an inflexible right line AC, supposed void of gravity or weight, and suspended from a fixed point or centre C, about which it moves.



A Compound PENDULUM, in Theory, is a pendulum consisting of several weights moveable about one common centre of motion, but connected together so as to retain the same distance both from one another, and from the centre about which they vibrate.

The Doctrine and Laws of Pendulums.—1. A pendulum raised to B, through the arc of the circle AB, will fall, and rise again, through an equal arc, to a point equally high, as D; and thence will fall to A, and again rise to B; and thus continue rising and falling perpetually, supposing neither friction nor resistance. For it is the same thing, whether the body fall down the inside of the curve BAD, by the force of gravity, or be retained in it by the action of the string; as they will both have the same effect; and it is otherwise known, from the oblique descents of bodies, that the body will descend and ascend along the curve in the manner above described.

Experience also confirms this theory, in any finite number of oscillations. But if they be supposed infinitely continued, a difference will arise. For the resistance of the air, and the friction and rigidity of the string about the centre C, will take off part of the force acquired in falling; hence it happens that it does not rise precisely to the same point from whence it fell. Thus, the ascent continually diminishing the oscillation, this will be at last stopped, and the pendulum will hang at rest in its natural direction, which is perpendicular to the horizon.

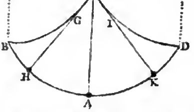
Now as to the real time of oscillation in a circular arc BAD: it is demonstrated by mathematicians, that if $p = 3{\cdot}1416$, denote the circumference of a circle whose diameter is 1; $g = 16\frac{1}{12}$ feet or 193 inches, the space a heavy body falls in the first second of time, in our latitude; and $r =$ CA the length of the pendulum; also $a =$ AE the height of the arch of vibration; then the time of each oscillation in the arc BAD will be equal to $p\sqrt{\frac{r}{2g}} \times$ into the series $1 + \frac{1^2a}{2^2d} + \frac{1^2.3^2a^2}{2^2.4^2d^2} + \frac{1^2.3^2.5^2a^3}{2^2.4^2.6^2d^3}$ &c, where $d = 2r$ is the diameter of the arc described, or twice the length of the pendulum.

And here, when the arc is a small one, as in the case of the vibrating pendulum of a clock, all the terms of this series after the 2d may be omitted, on account of their smallness; and then the time of a whole vibration will be nearly equal to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{a}{8r})$.

So that the times of vibration of a pendulum in different small arcs of the same circle, are as $8r + a$, or 8 times the radius, added to the versed sine of the semiarc.

And farther, if D denote the number of degrees in the semiarc AB, whose versed sine is a, then the quantity last mentioned, for the time of a whole vibration, is changed to $p\sqrt{\frac{r}{2g}} \times (1 + \frac{D^2}{52524})$. And therefore the times of vibration in different small arcs, are as $52524 + D^2$, or as the number 52524 added to the square of the number of degrees in the semiarc AB. See my Tracts, vol. 3, prob. 15, pa. 338.

2. Let CB be a semicycloid, having its base EC parallel to the horizon, and its vertex B downwards; and let CD be the other half of the cycloid, in a similar position to the former. Now suppose a pendulum string, of the same length with the curve of each semicycloid BC, or CD, having its end fixed in C, and the thread applied all the way close to the cycloidal curve BC, and consequently the body or pendulum weight coinciding with the point B. If now the body be let go from B, it will descend by its own gravity, and in descending it will unwind the string from off the arch BC, as at the position CGH; and the ball H will describe a semicycloid BHA, equal and similar to BGC, when it has arrived at the lowest point A; after which, it will continue its motion, and ascend, by another equal and similar semicycloid AKD, to the same height D, as it fell from at B, the string now wrapping itself upon the other arch CID. From D it will descend again, and pass along the whole cycloid DAB, to the point B; and thus perform continual successive oscillations between B and D, in the curve of a cycloid; as it before oscillated in the curve of a circle, in the former case.



This contrivance, to make the pendulum oscillate in the curve of a cycloid, is the invention of the celebrated Huygens, to make the pendulum perform all its vibrations in equal times, whether the arch, or extent of the vibration be great or small; which is not the case in a circle, where the larger arcs take a longer time to run through them, than the smaller ones do, as is well known both from theory and practice.

It should be observed however, that in speaking of the equal times of vibrations in cycloidal arcs, the string by which the body is suspended is considered void of gravity and resistance, and as this is not absolutely true, it follows that theory and practice will be a little at variance on this head.

The chief properties of the cycloidal pendulum then, as demonstrated by Huygens, are the following. 1st, That the time of an oscillation in all arcs, whether larger or smaller, is always the same quantity, viz, whether the body begin to descend from the point B, and describe the semiarc BA; or that it begins at H, and describes the arc HA; or that it sets out from any other point; as it will still descend to the lowest point A in exactly the same time. And it is farther proved, that the time of a whole vibration through any double arc BAD, or HAK, &c, is in proportion to the time in which a heavy body will fall freely, by the force of gravity, through a space equal to $\frac{1}{2}$AC, half the length of the pendulum, as the circumference of a circle is to its diameter. So that, if $g = 16\frac{1}{12}$ feet denote the space a heavy body falls in the first second of time, $p = 3.1416$ the circumference of a circle whose diameter is 1, and $r =$ AC the length of the pendulum; then, because, by the nature of descents by gravity, $\sqrt{g} : \sqrt{\frac{1}{2}r} :: 1'' : \sqrt{\frac{r}{2g}}$, that is the time in which a body will fall through $\frac{1}{2}r$, or half the length of the pendulum; therefore, by the above proportion, as $1 : p :: \sqrt{\frac{r}{2g}} : p\sqrt{\frac{r}{2g}}$, which is the time of an entire oscillation in the cycloid.

And this conclusion is confirmed by experience. For example, if it were required to find the length of the pendulum that will so oscillate in one second; this will give the equation $p\sqrt{\frac{r}{2g}} = 1$; which reduced, gives $r = \frac{2g}{p^2} = \frac{386}{3.1416^2}$ inches $= 39.11$ or $39\frac{1}{8}$ inches, for the length of the seconds pendulum; which the best experiments show to be about $39\frac{1}{8}$ inches.

3. Hence also, we have a method of determining, from the experimented length of a pendulum, the space a heavy body will fall perpendicularly through in a given time: for, since $p\sqrt{\frac{r}{2g}} = 1$, therefore, by reduction, $g = \frac{1}{2}p^2r$ is the space a body will fall through in the first second of time, when r denotes the length of the seconds pendulum; and as constant experience shows that this length is nearly $39\frac{1}{8}$ inches, in the latitude of London, in this case g or $\frac{1}{2}p^2r$ becomes $\frac{1}{2} \times 3.1416^2 \times 39\frac{1}{8} = 193.07$ inches $= 16\frac{1}{12}$ feet, very nearly, for the space a body will fall in the first second of time, in the latitude of London: a fact which has been abundantly confirmed by experiments made there. And in the same manner, Mr. Huygens found the same space fallen through at Paris, to be 15 French feet.

The whole doctrine of pendulums, oscillating between two semicycloids, both in theory and practice, was delivered by that author, in his Horologium Oscillatorium, sive Demonstrationes de Motu Pendulorum. And every thing that regards the motion of pendulums has since been demonstrated in different ways, and particularly by Newton, who has given an admirable theory on the subject, in his Principia, where he has extended to epicycloids the properties demonstrated by Huygens of the cycloids.

4. As the cycloid may be considered as coinciding, in A, with any small arc of a circle described from the centre C, passing through A, where it is known the two curves have the same radius and curvature; therefore the time in the small arc of such a circle, will be nearly equal to the time in the cycloid; so that the times in very small circular arcs are equal, because these small arcs may be considered as portions of the cycloid, as well as of the circle. And this is one great reason why the pendulums of clocks are made to oscillate in as small arcs as possible, viz, that their oscillations may be the nearer to a constant equality.

This may also be deduced from a comparison of the times of vibration in the circle, and in the cycloid, as laid down in the foregoing articles. It has there been shown, that the times of vibration in the circle and cycloid are thus, viz,

time in the circle nearly $p\sqrt{\frac{r}{2g}} \times (1 + \frac{a}{8r})$,

time in the cycloidal arc $p\sqrt{\frac{r}{2g}}$;

where it is evident, that the former always exceeds the latter in the ratio of $1 + \frac{a}{8r}$ to 1; but this ratio always approaches nearer to an equality, as the arc, or as its versed sine a, is smaller; till at length, when it is very small, the term $\frac{a}{8r}$ may be omitted, and then the times of vibration become both the same quantity, viz, $p\sqrt{\frac{r}{2g}}$.

Farther, by the same comparison, it appears, that the time lost in each second, or in each vibration of the seconds pendulums, by vibrating in a circle, instead of a cycloid, is $\frac{a}{8r}$, or $\frac{D^2}{52524}$; and consequently the time lost in a whole day of 24 hours, is $\frac{5}{3}D^2$ nearly. In like manner, the seconds lost per day by vibrating in the arc of d degrees, is $\frac{5}{3}d^2$. Therefore if the pendulum keep true time in one of these arcs, the seconds lost or gained per day, by vibrating in the other, will be $\frac{5}{3}(D^2 - d^2)$. So, for example, if a pendulum measure true time in an arc of 3 degrees, on each side of the lowest point, it will lose $11\frac{2}{3}$ seconds a day by vibrating 4 degrees; and $26\frac{2}{3}$ seconds a day by vibrating 5 degrees; and so on.

5. The action of gravity is less in those parts of the earth where the oscillations of the same pendulum are slower, and greater where these are swifter; for the time of oscillation is reciprocally proportional to $\sqrt{g}$. And it being found by experiment, that the oscillations of the same pendulum are slower near the equator, than in places farther from it; it follows that the force of gravity is less there; and consequently the parts about the equator are higher or farther from the centre, than the other parts; and the shape of the earth is not a true sphere, but somewhat like an oblate spheroid, flatted at the poles, and raised gradually towards the equator. And hence also the times of the vibration of the same pendulum, in different latitudes, afford a method of determining the true figure of the earth, and the proportion between its axis and the equatorial diameter.

Thus, M. Richer found by an experiment made in the island of Cayenne, about 4 degrees from the equator, where a pendulum 3 feet $8\frac{3}{5}$ lines long, which at Paris vibrated seconds, required to be shortened a line and a quarter to make it vibrate seconds. And many other observations have confirmed the same principle. See Newton's Principia, lib. 3, prop. 20. By comparing the different observations of the French astronomers, Newton apprehends that 2 lines may be considered as the length a seconds pendulum ought to be decreased at the equator.

From some observations made by Mr. Campbell, in 1731, in Black-river, in Jamaica, 18° north latitude, it is collected, that if the length of a simple pendulum that swings seconds in London, be 39·126 English inches, the length of one at the equator would be 39·00, and at the poles 39·206. Philos. Trans. numb. 432.

And hence Mr. Emerson has computed the following Table, showing the length of a pendulum that swings seconds at every 5th degree of latitude, as also the length of the degree of latitude there, in English miles.

Degrees of Lat.	Length of Pendulum.	Length of the Degree.
	inches.	miles.
0	39·027	68·723
5	39·029	68·730
10	39·032	68·750
15	39·036	68·783
20	39·044	68·830
25	39·057	68·882
30	39·070	68·950
35	39·084	69·020
40	39·097	69·097
45	39·111	69·176
50	39·126	69·256
55	39·142	69·330
60	39·158	69·401
65	39·168	69·467
70	39·177	69·522
75	39·185	69·568
80	39·191	69·601
85	39·195	69·620
90	39·197	69·628

Capt. John Warren has lately made experiments on pendulums, at Madras, latitude 13° 4′ 12″, for which place he concludes the length of the seconds pendulum to be 39·02627 inches. He farther deduces the length at the equator to be 38·987 or 39 nearly, and that at the pole 39·207; hence he deduces the effect of gravity, in one second of time, to be at the equator 16·0328 feet, and at the poles 16·1233 feet; and hence also he deduces the ellipticity of the earth's figure to be $\frac{1}{311}$ nearly. See the Asiatic Researches, vol. xi, art. 5.

6. If two pendulums vibrate in similar arcs, the times of vibration are in the sub-duplicate ratio of their lengths. And the lengths of pendulums vibrating in similar arcs, are in the duplicate ratio of the times of a vibration directly; or in the reciprocal duplicate ratio of the number of oscillations made in any one and the same time. For, the time of vibration t being as $p\sqrt{\frac{r}{2g}}$, where p and g are constant or given, therefore t is as $\sqrt{r}$, and r as t^2. Hence therefore the length of a half-second pendulum will be $\frac{1}{4}r$ or $\frac{39\frac{1}{8}}{4} = 9·781$ inches; and the length of the quarter-second pendulum will be $\frac{1}{16}r = \frac{39\frac{1}{8}}{16} = 2·445$ inches; and so of others.

7. The foregoing laws, &c, of the motion of pendulums cannot strictly hold good, unless the thread that sustains the ball be void of weight, and the gravity of the whole ball be collected into a point. In practice therefore, a very fine thread, and a small ball, but of a very heavy matter, should be used. But a thick thread, and a bulky ball, disturb the motion very much; for in that case the simple pendulum becomes a compound one; it being much the same thing, as if several weights were applied to the same inflexible rod in several places.

8. M. Krafft, in the new Petersburg Memoirs, vols 6 and 7, has given the result of many experiments on pendulums, made in different parts of Russia, with deductions from them, from which he derives this theorem: If x be the length of a pendulum that swings seconds in any given latitude l, and in a temperature of 10 degrees of Reaumur's thermometer; then will the length of that pendulum, for that latitude, be thus expressed, viz,
$x = (439·178 + 2·321 \times \sin.^2 l)$ lines of a French foot. And this expression agrees very nearly, not only with all the experiments made on the pendulum in Russia, but also with those of Mr. Graham, and those of Mr. Lyons in 79° 50′ north latitude, where he found its length to be 441·38 lines. See OBLATENESS.

Simple PENDULUM, in Mechanics, an expression commonly used among artists, to distinguish such pendulums as have no provision for correcting the effects of heat and cold, from those that have such provision. Also Simple Pendulum, and Detached Pendulum, are terms sometimes used to denote such pendulums as are not connected with any clock, or clock-work.

Compound PENDULUM, in Mechanics, is a pendulum whose rod is composed of two or more wires or bars of metal. These, by undergoing different degrees of expansion and contraction, when exposed to the same heat or cold, have the difference of expansion or contraction made to act in such manner as to preserve constantly the same distance between the point of suspension, and centre of oscillation, though exposed to very different and various degrees of heat or cold. There are a great variety of constructions for this purpose; but they may be all reduced to the Gridiron, the Mercurial, and the Lever Pendulum.

It may be just observed by the way, that the vulgar method of remedying the inconvenience arising from the extension and contraction of the rods of common pendulums, is by applying the bob, or small ball, with a screw, at the lower end; by which means the pendulum is at any time made longer or shorter, as the ball is screwed downwards or upwards, and thus the time of its vibration is kept continually the same.

Angular PENDULUM, is formed of two pieces or legs, like a sector, and suspended by the angular point. This form has been invented to diminish the length of the common pendulum, and at the same time to preserve, or even increase the time of vibration. In this pendulum, the time of vibration depends on the length of the legs, and on the angle contained between them conjointly, the duration of the time of vibration increasing with the angle. For, the wider the opening between the two legs, the higher, it is evident, the centre of gravity ascends, as the shorter its distance below the point of suspension, and consequently the longer the distance of the centre of oscillation, or the slower the vibration, since the distance of the latter is reciprocally proportional to that of the former, by my Course of Mathematics, vol. 2, prop. 56. Hence, a pendulum of this construction may be made to oscillate in any given time whatever; for the distance of the centre of oscillation may be computed by that prop. and the time of vibration by prop. 30, or by the preceding parts of this article.—It may be easily shown, that in this kind of pendulum, the squares of the times of vibration, are directly as the secants of half the angles contained by the legs, or reciprocally as the cosines of the same. Hence, if a pendulum of this construction vibrates half seconds when its legs are close, it will vibrate whole seconds, when the legs are opened to an angle of $151^\circ\ 2\frac{1}{4}'$. If the two legs, for instance, be 15 inches long, and they make an angle of $150^\circ\ 23'$, the time of vibration will be 1 second; if the angle be increased to $178^\circ\ 49\frac{1}{2}'$, the time of vibration would be 5 seconds. See Gregory's Mechanics, vol. 1, pa. 269.

If an isosceles right-angled triangle be suspended at its vertex, the centre of oscillation will be in the middle of its base. And if a right-angled cone be suspended at its vertex, the centre of oscillation will be in the centre of its base. In either case therefore, the time of vibration will be the same as that of a simple pendulum whose length is equal to the altitude of the triangle or of the cone. Other pendulums, whose lengths shall be equal to the distance of the centre of oscillation, may be readily found from the known rules for the centre of oscillation. Thus, in a parabola vibrating in its own plane, and suspended at its vertex, the distance of the centre of oscillation below the vertex, is $\frac{5}{7}$ axis + $\frac{1}{3}$ parameter: and when this quantity is equal to the axis, the base of the parabola is to its axis, as 1·85164 to 1. For several other cases, see the part above quoted of Dr. Gregory's Mechanics.

The Conical or *Circular* PENDULUM. This is so called from the figure described by the string of the pendulum. This kind of pendulum was invented by M. Huygens, and is also claimed by Dr. Hooke. Its time of vibration depends both on the length of the string and on the magnitude of the circle described by the ball of the pendulum, or only on the altitude of the cone described, by the pendulum; for if a denote the altitude of the cone described, and $p = 3{\cdot}1416$, also $g = 16\frac{1}{12}$ feet, the distance freely fallen by a heavy body in 1 second of time; then it is well known that the time of each revolution of the pendulum, is $t = p\sqrt{\frac{2a}{g}} = 1{\cdot}108\sqrt{a}$ seconds nearly; and is therefore equal to double the time of vibration of a common simple pendulum, whose length is equal to the height of the cone.

Several other ingenious contrivances, by means of different rods and levers, as also hollow pendulums, &c, have been devised by several artists; as, for instance, by a Mr. Chandler, by Mr. Troughton, and by Mr. Adam Reid, an ingenious mechanist at Woolwich. This last contrivance is by a long steel rod, which passes easy through a hollow shorter rod of zinc, only connected together at their bottoms; the pendulum ball or weight being connected to the upper end of the zinc rod. As the long steel rod lengthens by heat, and lowers the ball, the zinc does the same, and raises the ball as much, by which the pendulum is preserved, of the same length in all temperatures, when once the rods have been adjusted together of properlengths.

The *Gridiron* PENDULUM was the invention of Mr. John Harrison, a very ingenious artist, and celebrated for his invention of the watch for finding the difference of longitude at sea, about the year 1725; and of several other time-keepers and watches since that time; for all which he received the parliamentary reward of between 20 and 30 thousand pounds. It consists of 5 rods of steel, and 4 of brass, placed in an alternate order, the middle rod being of steel, by which the pendulum ball is suspended; these rods of brass and steel, thus placed in an alternate order, and so connected with each other at their ends, that while the expansion of the steel rods has a tendency to lengthen the pendulum, the expansion of the brass rods, acting upwards, tends to shorten it. And thus, when the lengths of the brass and steel rods are duly proportioned, their expansions and contractions will exactly balance and correct each other, and so preserve the pendulum invariably of the same length. The simplicity of this ingenious contrivance is much in its favour; and the difficulty of adjustment seems the only objection to it. Mr. Harrison in his first machine for measuring time at sea, applied this combination of wires of brass and steel, to prevent any alterations by heat or cold, and in the machines or clocks he has made for this purpose, a like method of guarding against the irregularities arising from this cause is used.

The *Mercurial* PENDULUM was the invention of the ingenious Mr. Graham, in consequence of several experiments relating to the materials of which pendulums might be formed, in 1715. Its rod is made of brass, and branched towards its lower end, so as to embrace a cylindric glass vessel 13 or 14 inches long, and about 2 inches diameter; which being filled about 12 inches deep with mercury, forms the weight or ball of the pendulum. If upon trial the expansion of the rod be found too great for that of the mercury, more mercury must be poured into the vessel: if the expansion of the mercury exceeds that of the rod, so as to occasion the clock to go fast with heat, some mercury must be taken out of the vessel, so as to shorten the column. And thus may the expansion and contraction of the quicksilver in the glass be made exactly to balance the expansion and contraction of the pendulum rod, so as to preserve the distance of the centre of oscillation from the point of suspension invariably the same. Mr. Graham made a clock of this kind, and compared it with one of the best of the common sort, for 3 years together; when he found the errors of his to be only about one-eighth part of those of the latter. Philos. Trans. No. 392.

The *Lever* PENDULUM. From all that appears concerning this construction of a pendulum, we are inclined to believe that the idea of making the difference of the expansion of different metals operate by means of a lever, originated with Mr. Graham, who in the year 1737 constructed a pendulum, having its rod composed of one bar of steel between two of brass, which acted on the short end of a lever, to the other end of which, the ball or weight of the pendulum was suspended. This pendulum however was, upon trial, found to move by jerks; and therefore laid aside by the inventor, to make way for the mercurial pendulum, just mentioned.

Mr. Short informs us in the Philos. Trans. vol. 47, art. 88, that a Mr. Frotheringham, a quaker in Lincolnshire, caused a pendulum of this kind to be made: it consisted of two bars, one of brass, and the other of steel, fastened together by screws, with levers to raise or let down the bulb; above which these levers were placed. M. Cassini too, in the History of the Royal Academy of Sciences at Paris, for 1741, describes two kinds of pendulums for clocks, compounded of bars of brass and steel, and in which he applies a lever to raise or let down the bulb of the pendulum, by the expansion or contraction of the bar of brass.

Mr. John Ellicott also, in the year 1738, constructed a pendulum on the same principle, but differing from Mr. Graham's in many particulars. The rod of Mr. Ellicott's pendulum was composed of two bars only; the one of brass, and the other of steel. It had two levers, each sustaining its half of the ball or weight; with a spring under the lower part of the ball to relieve the levers from a considerable part of its weight, and so to render their motion more smooth and easy. The one lever in Mr. Graham's construction was above the ball: whereas both the levers in Mr. Ellicott's were within the ball; and each lever had an adjusting screw, to lengthen or shorten the lever, so as to render the adjustment the more perfect. See the Philos. Trans. vol. 47, pa. 479; where Mr. Ellicott's methods of construction are described, and illustrated by figures.

Notwithstanding the great ingenuity displayed by these very eminent artists on this construction, it must further be observed, in the history of improvements of this nature, that Mr. Cumming, another eminent artist, has given, in his Essays on the Principles of Clock and Watch-work, Lond. 1766, an ample description, with plates, of a construction of a pendulum with levers, in which it seems he has united the properties of Mr. Graham's and Mr. Ellicott's, without being liable to any of the defects of either. The rod of this pendulum is composed of one flat bar of brass, and two of steel; he uses three levers within the ball of the pendulum; and, among many other ingenious contrivances, for the more accurate adjusting of this pendulum to mean time, it is provided with a small ball and screw below the principal ball or weight, one entire revolution of which on its screw will only alter the rate of the clock's going one second per day; and its circumference is divided into 30, one of which divisions will therefore alter its rate of going one second in a month.

PENDULUM *Clock*, is a clock having its motion regulated by the vibration of a pendulum. It is controverted between Galileo and Huygens, which of the two first applied the pendulum to a clock. For the pretensions of each, see CLOCK. After Huygens had discovered, that the vibration made in arcs of a cycloid, however unequal they might be in extent, were all equal in time; he soon perceived, that a pendulum applied to a clock, so as to make it describe arcs of a cycloid, would rectify the otherwise unavoidable irregularities of the motion of the clock; since, though the several causes of those irregularities should occasion the pendulum to make greater or smaller vibrations, yet, by virtue of the cycloid, it would still make them perfectly equal in point of time; and the motion of the clock governed by it, would therefore be preserved perfectly equable. But the difficulty was, how to make the pendulum describe arcs of a cycloid; for naturally the pendulum, being suspended by a fixed point, can only describe circular arcs about it.

Here M. Huygens contrived to fix the iron rod or wire, which bears the ball or weight, at the top to a silken thread, placed between two cycloidal cheeks, or two little arcs of a cycloid, made of metal. Hence the motion of vibration, applying successively from one of those arcs to the other, the thread, which is extremely flexible, easily assumes the figure of them, and by that means causes the ball or weight at the bottom to describe a just cycloidal arc.

This is doubtless one of the most ingenious and useful inventions many ages have produced: by means of which it has been asserted there have been clocks that would not vary a single second in several days: and the same invention also gave rise to the whole doctrine of involute and evolute curves, with the radius and degree of curvature, &c.

It is true, the pendulum is still liable to its irregularities, how minute soever they may be. The silken thread by which it was suspended, shortens in moist weather, and lengthens in dry; by which means the length of the whole pendulum, and consequently the times of the vibrations, are somewhat varied.

To obviate this inconvenience, M. Lahire, instead of a silken thread, used a little fine spring; which was not indeed subject to shorten and lengthen from those causes; yet he found it grew stiffer in cold weather, and then made its vibrations faster than in warm; to which also we may add its expansion and contraction by heat and cold. He therefore had recourse to a stiff wire or rod, firm from one end to the other. Indeed by this means he renounced the advantages of the cycloid; but he found, as he says, by experience, that the vibrations in circular arcs are performed in times as equal, provided they be not of too great extent, as those in cycloids. But the experiments of Sir Jonas Moore, and others, have demonstrated the contrary.

The ordinary causes of the irregularities of pendulums Dr. Derham ascribes to the alterations in the gravity and temperature of the air, which increase and diminish the weight of the ball, and by that means make the vibrations greater and less; an accession of weight in the ball being found by experiment to accelerate the motion of the pendulum; for a weight of 6 pounds added to the ball, Dr. Derham found made his clock gain 13 seconds every day.

A general remedy against the inconveniences of pendulums, is to make them long, the ball heavy, and to vibrate but in small arcs. These are the usual means employed in England; the cycloidal cheeks being generally neglected. See the foregoing article.

Pendulum clocks resting against the same rail have been found to influence each other's motion. See the Philos. Trans. No. 453, sect. 5 and 6, where Mr. Ellicott has given a curious and exact account of this phenomenon.

PENDULUM *Royal*, a name used among us for a clock, whose pendulum swings seconds, and goes 8 days without winding up; showing the hour, minute, and second. The numbers in such a piece are thus calculated. First cast up the seconds in 12 hours, which are the beats in one turn of the great wheel; and they will be found to be 43200 = 12 × 60 × 60. The swing-wheel must be 30, to swing 60 seconds in one of its revolutions; now let the half of 43200, viz 21600, be divided by 30, and the quotient will be 720, which must be separated into quotients. The first of these must be 12, for the great wheel, which moves round once in 12 hours. Now 720 divided by 12, gives 60, which may also be conveniently broken into two quotients, as 10 and 6, or 12 and 5, or 8 and 7½; which last is most convenient: and if the pinions be all taken 8, the work will stand as above.

8)	96 (	12
8)	64 (	8
8)	60 (	7½
		30

According to this computation, the great wheel will go round once in 12 hours, to show the hour; the next wheel once in an hour, to show the minutes; and the swing-wheel once in a minute, to show the seconds. See Clock-work.

Ballistic Pendulum. See Ballistic *Pendulum.*

Level Pendulum. See Level.

Pendulum *Watch.* See Watch.

PENETRABILITY, capability of being penetrated. See Impenetrability.

PENETRATION, the act by which one thing enters another, or takes up the place already possessed by another. The schoolmen define penetration the co-existence of two or more bodies, so that one is present, or has its extension in the same place as the other. Most philosophers hold the penetration of bodies absurd, i. e. that two bodies should be at the same time in the same place; and accordingly impenetrability is laid down as one of the essential properties of matter.—What is popularly called penetration, only amounts to the matter of one body's being admitted into the vacuity or pores of another. Such is the penetration of water through the substance of gold.

PENINSULA, in Geography, is a portion or extent of land which is nearly surrounded with water, being joined to the continent only by an isthmus, or narrow neck. Such is Africa, the greatest peninsula in the world, which is joined to Asia by an isthmus at the extremity of the Red Sea; such also is Peloponnesus, or the Morea, joined to Greece: and Jutland, &c. Peninsula is the same with what is otherwise called Chersonesus.

PENNY, a well-known copper coin, being the 12th part of a shilling. The penny was formerly a silver coin first struck in England by our Saxon ancestors, being the 240th part of their pound, and its true weight was about $22\frac{1}{2}$ grains troy.

In Etheldred's time, the penny was the 20th part of the troyounce, and equal in weight to our three pence; which value it retained till the time of Edward III.

Till the time of King Edward the first, the penny was struck with a cross so deeply sunk in it, that it might, on occasion, be easily broken, and parted into two halves, thence called halfpennies; or into four, thence called fourthings, or farthings. But that prince coined it without the cross; instead of which he struck round halfpence and farthings. Though there are said to be instances of such round halfpence having been made in the reign of Henry the first, if not also in that of the two Williams.

Edward the first also reduced the weight of the penny to a standard; ordering that it should weigh 32 grains of wheat, taken out of the middle of the ear. This penny was called the penny sterling; and 20 of them were to weigh an ounce; whence the penny became a weight as well as a coin.

By the 9th of Edward the 3d, it was diminished to the 26th part of the troy ounce; by the 2d of Henry the 6th it was the 32d part; by the 5th of Edward the 4th, it became the 40th, and also by the 36th of Henry the 8th, and afterwards, the 45th; but by the 2d of Elizabeth, 60 pence were coined out of the ounce, and during her reign 62, which last proportion is still observed in our times.

The French penny, or denier, is of two kinds; the Paris penny, called denier Parisis; and the penny of Tours, called denier Tournois.

The Dutch penny, called penninck, or pening, is a real money, worth about one-fifth more than the French penny Tournois. The penninck is also used as a money of account, in keeping books by pounds, florins, and patards; 12 penninks make the patard, and 20 patards the florin.

At Hamburg, Nuremberg, &c, the penny, or pfennig of account, is equal to the French penny Tournois. Of these, 8 make the krieuk; and 60 the florin of those cities; also 90 the French crown, or 4s. 6d. sterling.

Penny-*Weight,* a troy weight, being the 20th part of an ounce, containing 24 grains; each grain weighing a grain of wheat gathered out of the middle of the ear, well dried. The name took its rise from its being actually the weight of one of our ancient silver pennies. See the foregoing article.

PENTAGON, in Geometry, a plane figure consisting of five angles, and consequently five sides also. If the angles be all equal, it is a regular pentagon. It is a remarkable property of the pentagon, that its side is equal in power to the sides of a hexagon and a decagon inscribed in the same circle; that is, the square of the side of the pentagon, is equal to both the squares taken together of the sides of the other two figures; and consequently those three sides will constitute a right-angled triangle. Euclid, l. 13, prop. 10.—Pappus has also demonstrated, that 12 regular pentagons contain more than 20 triangles inscribed in the same circle; lib. 5, prop 45.—The dodecahedron, which is the fourth regular body or solid, is contained under 12 equal and regular pentagons.

To find the Area of a Regular Pentagon. Multiply the square of its side by 1·7204774, or by $\frac{5}{4}$ of the tangent of 54°, or by $\frac{5}{4}\sqrt{(1 + \frac{2}{5}\sqrt{5})}$. Hence, if s denote the side of the pentagon, its area will be $1·7204774s^2 = \frac{5}{4}s^2\sqrt{(1 + \frac{2}{5}\sqrt{5})} = \frac{5}{4}s^2 \times \text{tang. } 54°$.

PENTAGRAPH, otherwise called a parallelogram, a mathematical instrument for copying designs, prints, plans, &c, in any proportion. The common pentagraph (plate 24, fig. 2) consists of four rulers or bars, of metal or wood, two of them from 15 to 18 inches long, the other two half that length. At the ends, and in the middle, of the long rulers, as also at the ends of the shorter ones, are holes, on the exact fixing of which the perfection of the instrument chiefly depends. Those in the middle of the long rulers, are to be at the same distance from those at the end of the long ones, and those of the short ones; so that, when put together, they may always make a parallelogram.

The instrument is fitted together for use, by several little pieces, particularly a little pillar, No. 1, having at one end a nut and screw, joining the two long rulers together; and at the other end a small knot for the instrument to slide on. The piece No. 2 is a rivet with a screw and nut, by which each short ruler is fastened to the middle of each long one. The piece No. 3 is a pillar, one end of which, being hollowed into a screw, has a nut fitted to it; and at the other end is a worm to screw into the table; when the instrument is to be used, it joins the ends of the two short rulers. The piece No. 4 is a pen, or pencil, or porteravon, screwed into a little pillar. Lastly, the piece No. 5 is a brass point, moderately blunt, screwed likewise into a little pillar.

Use of the Pentagraph.—1. To copy a design in the same size or scale as the original. Screw the worm No. 3 into the table; lay a paper under the pencil No. 4, and the design under the point No. 5. This done, conduct the point over the several lines and parts of the design, and the pencil will draw or repeat the same on the paper.

2. When the design is to be reduced, for example to half the scale; the worm must be placed at the end of the long ruler No. 4, and the paper and pencil in the middle. In this situation conduct the brass point over the several lines

of the design, as before; and the pencil at the same time will draw its copy in the proportion required; the pencil here only moving half the lengths that the point moves.

3. On the contrary, when the design is to be enlarged to a double size; the brass point, with the design, must be placed in the middle at No. 3, the pencil and paper at the end of the long ruler, and the worm at the other end.

4. To reduce or enlarge in other proportions, there are holes drilled at equal distances on each ruler; viz, all along the short ones, and half way of the long ones, for placing the brass point, pencil, and worm, in a right line in them; i. e. if the piece carrying the point be put in the third hole, the other two pieces must be put each in its third hole; &c.

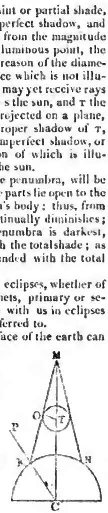
PENTANGLE, a plane figure of five angles, or the same as the PENTAGON.

PENUMBRA, in Astronomy, a faint or partial shade, in an eclipse, observed between the perfect shadow, and the full light. The penumbra arises from the magnitude of the sun's body: were he only a luminous point, the shadow would be all perfect; but by reason of the diameter of the sun it happens, that a place which is not illuminated by the whole body of the sun, may yet receive rays from some part of it. Thus, suppose S the sun, and T the moon, and the shadow of the latter projected on a plane, as GH (plate 24, fig. 3). The true proper shadow of T, viz GH, will be encompassed with an imperfect shadow, or penumbra, HL and GE, each portion of which is illuminated by an entire hemisphere of the sun.

The degree of light or shade of the penumbra, will be more or less in different parts, as those parts lie open to the rays of a greater or less part of the sun's body: thus, from L to H, and from E to G, the light continually diminishes; in the confines of G and H, the penumbra is darkest, and becomes lost and confounded with the total shade; as near E and L it is thin and confounded with the total light.

A penumbra must be found in all eclipses, whether of the sun, the moon, or the other planets, primary or secondary; but it is most considerable with us in eclipses of the sun; which is the case here referred to.

To determine how much of the surface of the earth can be involved in the penumbra, let the apparent semidiameter of the sun be supposed the greatest, or about 16′ 20″, which is when the earth is in her perihelion; also let the moon be in her apogee, and therefore at her greatest distance from the earth, or about 64 of the earth's semidiameters. Let KNC be the earth, T the moon, and MKN the penumbra, involving the part of the earth from K to N, which it is required to find. Here then are given the angle KMC = 16′ 20″, TC = 64, KC = 1,



and OT = $\frac{3}{11}$ of KC. Hence, in the right-angled triangle OTM, as sin. OMT : radius : : OT : TM = 210½OT = 58KC nearly. Therefore MC = MT + TC = 58 + 64 = 122 semidiameters of the earth. Then, in the triangle KMC, there are given KC = 1, and MC = 122, also the angle KMC = 16′ 20″, to find the angle C; thus, as

KC : MC : : sin. ∠KMC : sin. ∠MKP =	35°	25′	35″;
from this take the angle ∠KMC -	0	16	20,
leaves the ∠C - - -	35	9	11,

the double of which is the arc KN 70° 18′ 22″, or nearly a space of 4866 miles in diameter.

PERAMBULATOR, an instrument for measuring distances; called also pedometer, way-wiser, and surveying wheel. This wheel is contrived to measure out a pole, or 16½ feet, in making two revolutions; consequently its circumference is 8¼ feet, and its diameter 2·626 feet, or 2 feet 5¼ inches and $\frac{12}{1000}$ parts, very nearly. It is either driven forward by two handles, by a person walking; or is drawn by a coach wheel, &c, to which it is attached by a pole. It contains various movements, by wheels, or clock-work, with indices on its face, which is like that of a clock, to point out the distance passed over, in miles, furlongs, poles, yards, &c. Its advantages are, its readiness and expedition; being very useful for measuring roads and great distances on level ground. See the fig. plate 21, fig. 6.

PERCH, in Surveying, a square measure, being the 40th part of a rood, or the 160th part of an acre; that is, the square of a pole or rod, of the length of 5½ yards, or 16½ feet.

PERCH is by some also made to mean a measure of length; being the same as the rod or pole of 5½ yards or 16½ feet long. But it is better, for preventing confusion, to distinguish them.

PERCUSSION, in Physics, the impression a body makes in falling or striking upon another; or the shock or collision of two bodies, which meeting alter each other's motion.—Percussion is either direct or oblique. It is also either between elastic or nonelastic bodies, which have each their different laws. It is true, we know of no bodies in nature that are either perfectly elastic or the contrary; but all partaking of that property in different degrees; even the hardest and the softest being not entirely divested of it. But, for the sake of perspicuity, it is usual, and proper, to treat of these under two distinct heads.

Direct PERCUSSION is that in which the impulse is made in the direction of a line perpendicular at the place of impact, and which also passes through the common centre of gravity of the two striking bodies. As is the case in two spheres, when the line of the direction of the stroke passes through the centres of both spheres; for then the same line, joining their centres, passes perpendicularly through the point of impact. And

Oblique PERCUSSION, is that in which the impulse is made in the direction of a line that does not pass through the common centre of gravity of the striking bodies; whether that line of direction is perpendicular to the place of impact, or not. The force of percussion is the same as the momentum, or quantity of motion, and is represented by the product arising from the mass or quantity of matter moved, multiplied by the velocity of its motion; and that without any regard to the time or duration of action; for its action is considered totally independent of time, or but as for an instant, or an infinitely small time.

This leads us to consider a question that has been greatly canvassed among philosophers and mathematicians, viz, what is the relation between the force of percussion and mere pressure or weight? Now let M denote any mass, body, or weight, having no motion or velocity, but simply its pressure; then will that pressure or force be denoted by M itself, if it be considered as acting for some certain finite assignable time; but, considered as a force of percussion, that is, as acting but for an infinitely small time, its velocity being 0, or nothing, its percussive force will be 0 × M, that is 0, or nothing; and is therefore incomparable with any percussive force whatever. But if we consider the two forces, viz, of percussion and pressure, with respect to the effects they produce: we shall find that there are instances in which they appear to resemble each other. Those who argue that the two forces are totally incomparable both in their nature and effects, support their hypothesis in the following manner. The intensity of any force is very properly estimated by the effect it produces in a given time: but the effect of the pressure M, in 0 time, or an infinitely small time, is nothing at all; that is, it will not, in an infinitely small time, produce, for example, any motion, either in itself, or in any other body: its intensity therefore, as its effect, is infinitely less than any the smallest force of percussion. It is true, indeed, that we see motion and other considerable effects produced by mere pressure, and to counteract which requires the opposition of some considerable percussive force: but then it must be observed, that the former has been an infinitely longer time than the latter in producing its effect; and it is no wonder in mathematics that an infinite number of infinitely small quantities makes up a finite one. It has therefore only been for want of considering the circumstance of time, that any question could have arisen on this head. Hence it is said that these two forces are related to each other, only as a surface is to a solid or body: by the motion of the surface through an infinite number of points, or through a finite right line, a solid or body is generated; and by the action of the pressure for an infinite number of moments, or for some finite time, a quantity equal to a given percussive force is generated: but the surface itself is infinitely less than any solid, and the pressure infinitely less than any percussive force. This point, say they, may be easily illustrated by some familiar instances, which prove at least the enormous disproportion between the two forces, if not also their absolute incomparability. And first, the blow of a small hammer, upon the head of a nail, will drive the nail into a board; when it is hard to conceive any weight so great as will produce a like effect, i. e. that will sink the nail as far into the board, at least unless it is left to act for a very considerable time: and even after the greatest weight has been laid as a pressure on the head of the nail, and has sunk it as far as it can as to sense, by remaining for a long time there without producing any farther sensible effect; let the weight be removed from the head of the nail, and instead of it, let it be struck a small blow with a hammer, and the nail will immediately sink farther into the wood. Again, it is also well known, that a ship-carpenter, with a blow of his mallet, will drive a wedge in below the greatest ship, lying aground, and so overcome her weight, and lift her up. Lastly, let us consider a man with a club to strike a small ball, upwards or in any other direction; it is evident that the ball will acquire a certain determinate velocity by the blow, suppose that of 10 feet per second, or minute, or any other time whatever: now it is a law, universally allowed in the communication of motion, that when different bodies are struck with equal forces, the velocities communicated are reciprocally as the weights of the bodies that are struck; that is, that a double body, or weight, will acquire half the velocity from an equal blow; a body 10 times as great, one 10th of the velocity; a body 100 times as great, the 100th part of the velocity; a body a million times as great, the millionth part of the velocity; and so on without end: whence it follows, that there is no body or weight, how great soever, but will acquire some finite degree of velocity, and be overcome, by any given small finite blow, or percussion.

Those however that take the contrary side of the question; in answer to what is above stated, make the following reply. We do not, say they, contend for the absolute comparability of percussion and pressure; all we assert is, that there are instances in which they produce similar effects, and as forces can only be compared by their effects, it is improper to consider them as absolutely incongruous: it is true that percussion is a momentary cause, but the effect it produces is not instantaneous; thus the blow of a hammer may be considered as acting for an indefinitely small portion of time, but the effect it produces can only be complete after a certain finite time; and if, in this time, a certain quantity of pressure will produce the same motion in any body, then it follows that there may be instances in which the effects of these two forces are equal, and consequently that they are comparable with each other: and to this it may be farther added, that though we allow percussion to be an instantaneous force, yet, must that body by which it is communicated have been in motion for a certain time, in order to have attained the velocity with which it strikes, and to which alone we attribute its superior force; there seems therefore no reason why pressure should not be allowed to act for the same time in any cases when we are comparing the effect of the two forces with each other. In fact, the difference between percussion and pressure seems to consist in this, that, in the latter force, the whole mass of the body is acting by continual and successive impulses, whereas in the former, these efforts, as it were, are all collected into one sum, and then instantaneously applied. And the reason why they do not produce the same effect is, that when any resistance to motion is made, either by friction or otherwise, a certain force is necessary to overcome the opposing force, before any absolute motion can ensue, and no force short of that by which the body is opposed will produce any effect whatever, however often it may be repeated; and therefore, when the opposing force is greater than the pressing force, no motion can ensue; but the momentum of the moving body, or the percussion, being as it were the accumulated sum of all the successive efforts of the pressing body, there is a sufficient quantity of action, first to overcome the opposing force, and the overplus is then employed in the generation of motion. It is therefore to this circumstance that we must attribute the apparent incongruity of percussion and pressure, and not to any existing difference in the nature of the two forces; for the very same cause will also prevent the comparison of a greater and less percussive force. For example, after a pile-engine has been employed for a certain time in driving a pile, until its action upon it is very trifling, it would be in vain for a man with a mallet, to endeavour to drive the pile an inch lower, because he could not produce such a momentum as is equivalent to the resisting force acting against the pile, and consequently it would remain in its place, however long his efforts may continue, for the effect of each blow ceases with it, and none of these, taken singly, having any motion, the same is true whatever may be the number of times that they are repeated; but if the ram of the pile-engine be again employed, the desired effect may be produced: the effect of this last then, in this case, is infinitely greater than the former, yet no one will be bold enough to assert that these two percussive forces are absolutely incomparable on this account.

Much more might be advanced in support of the hypothesis, that pressure and percussion are not incongruous in their nature, and that we are only prevented from comparing them, or their effects, by certain circumstances that arise in the application of the two forces to practical purposes.

The nature and laws of percussion have been investigated by Aristotle, Galileo, Descartes, Huygens, and others. Aristotle started the idea that percussion and weight are not comparable; and most moderns have acquiesced in that opinion.

It appears that Descartes had some ideas of the laws of percussion; though it must be acknowledged, in some cases perhaps wide of the truth. The first who gave the true laws of motion in non-elastic bodies, was Doctor Wallis, in the Philos. Trans. numb. 43, where he also shows the true cause of reflections in other bodies, and proves that they proceed from their elasticity. Not long after, the celebrated sir Christopher Wren and Mr. Huygens imparted to the Royal Society the laws that are observed by perfectly elastic bodies, and gave exactly the same construction, though each was ignorant of what the other had done. And all those laws, thus published in the Philos. Trans. without demonstration, were afterwards demonstrated by Dr. Keill, in his Philos. Lect. in 1700; and they have since been followed by a number of other authors.

We have before observed that in percussion, we distinguish at least three several kinds of bodies; the perfectly hard, the perfectly soft, and the perfectly elastic. The two former are considered as utterly void of elasticity; having no force to separate them, or throw them off from each other again, after collision; and therefore either remaining at rest, or else proceeding uniformly forward together as one body or mass of matter. The laws of percussion therefore to be considered, are of two kinds: those for elastic, and those for non-elastic bodies.

The one only general principle, for determining the motions of bodies from percussion, and which belongs equally to both the kinds of bodies, i. e. both the elastic and non-elastic, is this: viz, that there exists in the bodies the same momentum, or quantity of motion, estimated in any one and the same direction, both before the stroke and after it. And this principle is the immediate result of the third law of nature or motion, that reaction is equal to action, and in a contrary direction; whence it happens that whatever motion is communicated to one body by the action of another, exactly the same motion doth this latter lose in the same direction, or exactly the same does the former communicate to the latter in the contrary direction.—From this general principle too it results, that no alteration takes place in the common centre of gravity of bodies by their actions on one another; but that the said common centre of gravity perseveres in the same state, whether of rest or of uniform motion, both before and after the shock of the bodies.

Now, from either of these two laws, viz, that of the preservation of the same quantity of motion, in one and the same direction, and that of the preservation of the same state of the centre of gravity, both before and after the shock, all the circumstances of the motions of both the kinds of bodies after collision may be estimated; in conjunction with their own peculiar and separate constitutions, namely, that of the one sort being elastic, and the other nonelastic.

The effects of these different constitutions, here alluded to, are these; that nonelastic bodies, on their shock, will adhere together, and either remain at rest, or else move together as one mass with a common velocity; or if elastic, they will separate after the shock with the very same relative velocity with which they met each other. The former of these consequences is evident, viz, that nonelastic bodies keep together as one mass after they meet; because there exists no power to separate them; and without a cause there can be no effect. And the latter consequence results immediately from the very definition and essence of elasticity itself, being a power always equal to the force of compression, or shock; and which restoring force therefore, acting the contrary way, will generate the same relative velocity between the bodies, or the same quantity of motion, as before the shock, and the same motion also of their common centre of gravity.

To apply now the general principle to the determination of the motions of bodies after their shock; let B and b be any two bodies, and V and v their respective velocities, estimated in the direction AD; which quantities V and v will be both positive if the bodies both move towards D, but one of them as v will be negative if the body b move towards A, and v will be $= 0$ if the body b be at rest. Hence then BV is the momentum of B towards D, and bv is the momentum of b towards D, whose sum is $BV + bv$, which is the whole quantity of motion in the direction AD, and which momentum must also be preserved after the impact.

Now if the bodies have no elasticity, they will move together as one mass $B + b$ after they meet, with some common velocity, which call y, in the direction AD; therefore the momentum in that direction after the shock, being the product of the mass and velocity, will be $(B + b) \times y$. But the momenta, in the same direction, before and after the impact, are equal, that is $BV + bv = (B + b)y$; from which equation any one of the quantities may be determined, when the rest are given. So, if we would find the common velocity after the stroke, it will be $y = \frac{BV + bv}{B + b}$, equal to the sum of the momenta divided by the sum of the bodies; which is also equal to the velocity of the common centre of gravity of the two bodies, both before and after the collision. The signs of the terms, in this value of y, will be all positive, as observed above, when the bodies move both the same way AD; but one term bv must be made negative when the motion of b is in the contrary direction; and that term will be absent or nothing, when b is at rest, before the shock.

Again, for the case of elastic bodies, which will separate after the stroke, with certain velocities, x and z, viz, x the velocity of B, and z the velocity of b after the collision, both estimated in the direction AD, which quantities will be either positive, or negative, or nothing, according to the circumstances of the masses B and b, with those of their celerities before the stroke. Hence then Bx and bz are the separate momenta after the shock, and $Bx + bz$ their sum, which must be equal to the sum $BV + bv$ in the same direction before the stroke: also $z - x$ is the relative velocity with which the bodies separate after the blow, and which must be equal to $V - v$ the same with which they meet; or, which is the same thing, that $V + x = v + z$; that is, the sum of the two velocities of the one body, is equal to the sum of the velocities of the other, taken before and after the stroke; which is another remarkable theorem. Hence then, for determining the two unknown quantities x and z, there are these two equations,

$$\text{viz, } BV + bv = Bx + bz,$$
$$\text{and } V - v = z - x;$$
$$\text{or } V + x = v + z;$$

the resolution of which equations gives those two velocities, as below,

$$\text{viz, } x = \frac{2bv + (B - b)V}{B + b},$$
$$\text{and } z = \frac{2BV - (B - b)v}{B + b}.$$

From these general values of the velocities, which are to be understood in the direction AD, any particular cases may easily be drawn. As, if the two bodies B and b be equal, then $B - b = 0$, and $B + b = 2B$, and the two velocities in that case become, after impulse, $x = v$, and $z = V$, the very same as they were before, but changed to the contrary bodies, i. e. the bodies have taken each other's velocity that it had before, and with the same sign also. So that, if the equal bodies were before both moving the same way, or towards D, they will do the same after, but with interchanged velocities. But if they before moved contrary ways, B towards D, and b towards A, they will rebound contrary ways, B back towards A, and b towards D, each with the other's velocity. And, lastly, if one body, as b, were at rest before the stroke, then the other B will be at rest after it, and b will go on with the motion that B had before. And thus may any other particular cases be deduced from the first general values of x and z.

We may now conclude this article with some remarks on these motions, and the mistakes of some authors concerning them. And first, we observe this striking difference between the motions that are communicated by elastic and by nonelastic bodies, viz, that a nonelastic body, by striking, communicates or continues exactly its whole momentum in the direction of its motion; as is evident. But the stroke of an elastic body may either communicate its whole motion to the body it strikes, or it may communicate only a part of it, or it may even communicate more than it had, so to speak. For, if the striking body remain at rest after the stroke, it has just lost all its motion, and therefore has communicated all it had; and if it still move forward in the same direction, it has still some motion left in that direction, and therefore has only communicated a part of what motion it had; but if the striking body rebound back, and move in the contrary direction, the other body has received not only the whole of the motion that the first had, but also as much more as the first has acquired in the contrary direction.

It has been denied by some authors, and in the Encyclopédie, that the same quantity of motion remains after the shock, as before it; and hence they seize an opportunity to reprehend the Cartesians for making that assertion, which they do, not only with respect to the case of two bodies, but also of all the bodies in the whole universe. And yet nothing is more true, if the motion be considered as estimated always in one and the same direcion, accounting that as negative, which is in the contrary or opposite direction. For it is a general law of nature, that no motion, nor force, can be generated, nor destroyed, nor changed, but by some cause which must produce an equal quantity in the opposite direction. And this being the case in one body, or two bodies, it must necessarily be the case in all bodies, and in the whole solar system, since all bodies act upon one another. And hence also it is manifest, that the common centre of gravity of the whole solar system must always preserve its original condition, whether it be of rest or of uniform motion; since the state of that centre is not changed by the mutual actions of bodies on each other, any more than their quantity of motion, in one and the same direction.

What may have led authors into the mistake above alluded to, which they bring no proof of, seems to be the discovery of M. Huygens, that the sums of the two products are equal, both before and after the shock, that are made by multiplying each body by the square of its velocity, viz, that $BV^2 + bv^2 = Bx^2 + bz^2$, where V and v are the velocities before the shock, and x and z the velocities after it. Such an expression, namely the product of the mass by the square of the velocity, is called the vis viva, or living force; and hence it has been inferred that the whole vis viva before the shock, or $BV^2 + bv^2$, is equal to that after the stroke, or $Bx^2 + bz^2$; which is indeed very true, as will be shown presently. But when they hence infer, that therefore the forces of bodies in motion are as the squares of the velocities, and that there is not the same quantity of motion between the two striking bodies, both before and after the shock, they are grossly mistaken, and thereby show that they are ignorant of the true derivation of the equation $BV^2 + bv^2 = Bx^2 + bz^2$. For this equation is only a consequence of the very principle above laid down, and which is not acceded to by those authors, viz, that the quantity of motion is the same before and after the shock, or that $BV + bv = Bx + bz$, the truth of which last equation they deny, because they think the former one is true, never considering that they may be both true, and much less that the one is a consequence of the other, and derived from it; which however is now found to be the case, as is proved in this manner:

It has been shown that the sum of the two momenta, in the same direction, before and after the stroke, are equal, or that $BV + bv = Bx + bz$; and also that the sum of the two velocities of the one body, is equal to the sum of those of the other, or that $V + x = v + z$; and it is now proposed to show that from these two equations there results the third equation $BV^2 + bv^2 = Bx^2 + bz^2$, or the equation of the living forces.

Now because $BV + bv = Bx + bz$, by transposition it is - - $BV - Bx = bz - bv$; which shows that the difference between the two momenta of the one body, before and after the stroke, is equal to the difference between those of the other body; which is another important theorem. But now, to derive the equation of the vis viva, set down the two foregoing equations, and multiply them together, so shall the products give the said equation required; thus,

Mult. $BV - Bx = bz - bv$, the equat. of the momenta,
by $V + x = z + v$, the equat. of the velocities,
produc. $BV^2 - Bx^2 = bz^2 - bv^2$,
or $BV^2 + bv^2 = Bx^2 + bz^2$,

the very equation of the vis viva required. See Keill's Lect. Philos. sect. 14, theor. 29, at the end. And for the geometrical determinations after impact, see the article Collision.

When the elasticity of the bodies is not perfect, but only partially so, as is the case with all the bodies we know of, the determination of the motions after collision may be determined in a similar manner. In this case also the sum of the momenta will still be the same, both before and after collision, but the velocities after will be less than in the case of perfect elasticity, in the ratio of the imperfection. Hence, with the same notation as before, the two equations will now be $BV + bv = Bx + by$, and $V - v = \frac{m}{n}(y - x)$, where m to n denotes the ratio of perfect to imperfect elasticity. And the resolution of these two equations, give the following values of x and y, viz, $x = V - \frac{m+n}{m} \cdot \frac{b}{B+b}(V - v)$, $y = v + \frac{m+n}{m} \cdot \frac{B}{B+b}(V - v)$, for the velocities of the two bodies after impact, in the case of imperfect elasticity; which would become the same as the former if n were $= m$.

Hence, if the two bodies B and b be equal, then $x = V - \frac{m+n}{2m}(V - v)$, and $y = v + \frac{m+n}{2m}(V - v)$, where the velocity lost by B is just equal to that gained by b. And if in this case b was at rest before the impact, viz $v = 0$, then the resulting motions would be $x = \frac{m-n}{2m}V$, and $y = \frac{m+n}{2m}V$, which are in the ratio of $m - n$ to $m + n$.

Also, if $m = n$, or the bodies perfectly elastic, then $x = 0$, and $y = V$; that is, B would be at rest, and b go on with the first motion of B.—Further, in this case also, the velocity of B before the impact, is to that of b after it, as V to $\frac{m+n}{2m}$ V, or as $2m$ to $m + n$. But if the bodies be now supposed to vibrate in circles, as pendulums, in which case the chords (C and c) of the arcs described, are known to be proportional to the velocities; then it will be $2m : m + n :: C : c$; hence $m : n :: C : 2c - C$. So that, by measuring these chords, of the arcs thus experimentally described, the ratio of m to n, or the degree of elasticity in the bodies, may be determined.

Centre of PERCUSSION, is the point in which the shock or impulse of a body which strikes another is the greatest that it can be. See CENTRE.—The centre of percussion is the same as the centre of oscillation, when the striking body moves round a fixed axis. See OSCILLATION.—But if all the parts of the striking body move with a parallel motion, and with the same velocity, then the centre of percussion is the same as the centre of gravity.

PERFECT NUMBER, is one that is equal to the sum of all its aliquot parts, when added together. Eucl. lib. 7, def. 22. As the number 6, which is $= 1 + 2 + 3$, the sum of all its aliquot parts; also 28, for $28 = 1 + 2 + 4 + 7 + 14$, the sum of all its aliquot parts. —It is proved by Euclid, in the last prop. of book the 9th, that if the common geometrical series of numbers 1, 2, 4, 8, 16, 32, &c, be continued to such a number of terms, as that the sum of the said series of terms shall be a prime number, then the product of this sum by the last term of the series will be a perfect number. The same rule may be otherwise expressed thus: If n denote the number of terms in the given series 1, 2, 4, 8, &c; then it is well known that the sum of all the terms of the series is $2^n - 1$, and it is evident that the last term is 2^{n-1}: consequently the rule becomes thus, viz, $2^{n-1} \times (2^n - 1) =$ a perfect number, whenever $2^n - 1$ is a prime number.

Now the sums of one, two, three, four, &c, terms of the series 1, 2, 4, 8, &c, form the series 1, 3, 7, 15, 31, &c; so that the number will be found perfect whenever the corresponding term of this series is a prime, as 1, 3, 7, 31 &c. Whence the table of perfect numbers may be found and exhibited as follows; where the 1st column shows the number of terms, or the value of n; the 2d column is the last term of the series 1, 2, 4, 8, &c, and is expressed by 2^{n-1}; the 3d column contains the corresponding sums of the said series, or the values of the quantity $2^n - 1$; which numbers in this 3d column are easily constructed by adding always the last number in this column to the next following number in the 2d column: and lastly, the 4th column shows the correspondent perfect numbers, or the values of $2^{n-1} \times (2^n - 1)$, the product of the numbers in the 2d and 3d columns, when $2^n - 1$, or the number in the 3d column, is a prime number; the products in the other cases being omitted, as not perfect numbers.

Values of n	Values of 2^{n-1}	Values of $2^n - 1$	Perf. Numbers, or $2^{n-1} \times (2^n - 1)$
1	1	1	1
2	2	3	6
3	4	7	28
4	8	15	——
5	16	31	496
6	32	63	——
7	64	127	8128

Hence the first four perfect numbers are found to be 6, 28, 496, 8128; and thus the table might be continued to find others; but the trouble would be very great, for want of a general method to distinguish which numbers are primes, as the case requires. Several learned mathematicians have endeavoured to facilitate this business, but hitherto with only a small degree of effect. After the foregoing four perfect numbers, there is a long interval before any more occur. The first eight are as follow, with the factors and products which produce them; being all the primes that are yet known.

The first perfect numbers.	Their values.
6 - - - - -	$= (2^2 - 1)\,2$
28 - - - - -	$= (2^3 - 1)\,2^2$
496 - - - - -	$= (2^5 - 1)\,2^4$
8128 - - - -	$= (2^7 - 1)\,2^6$
33550336 - - - -	$= (2^{13} - 1)\,2^{12}$
8589869056 - - -	$= (2^{17} - 1)\,2^{16}$
137438691328 - - -	$= (2^{19} - 1)\,2^{18}$

See several considerable tracts on the subject of perfect numbers in the Memoirs of the Petersburg Academy, vol. 2 of the new vols, and in several other volumes.

PERIÆCI. See PERIOECI.

PERIGÆUM, or PERIGEE, is that point of the orbit of the sun or moon, which is the nearest to the earth. In which sense it stands opposed to apogee, which is the most distant point from the earth.

PERIGEE, in the Ancient Astronomy, denotes a point in a planet's orbit, where the centre of its epicycle is at the least distance from the earth.

PERIHELION, PERIHELIUM, that point in the orbit of a planet or comet which is nearest to the sun. In which sense it stands opposed to aphelion, or aphelium, which is the highest or most distant point from the sun. Instead of this term, the ancients used perigeum; because they placed the earth in the centre.

PERIMETER, in Geometry, the ambit, limit, or outer bounds of a plane figure; being the sum of all the lines by which it is inclosed or formed. In circular figures, &c, instead of this term, the word circumference or periphery is used.

PERIOD, in Astronomy, the time in which a star or planet makes one revolution, or returns again to the same point in the heavens. The sun's, or properly the earth's tropical period, is 365 days 5 hours 48 minutes 45 seconds 30 thirds. That of the moon is 27 days 7 hours 43 minutes. That of the other planets as below.—There is a remarkable harmony between the distances of the planets from the sun, and their periods round him; the great law of which is, that the squares of the periodic times are always proportional to the cubes of their mean distances from the sun.

The periods, both tropical and sidereal, with the proportions of the mean distances of the several planets, are as follow:

Planets.	Tropical Periods.			Sidereal Periods.			Proport. Dists.
Mercury - -	87^d	23^h	14'	87^d	23^h	16'	36710
Venus - - -	224	16	42	224	16	49	72333
Earth - - -	365	5	49	365	6	9	100000
Mars - - -	686	22	18	686	23	31	152369
Vesta - - -	-	-	-	-	-	-	235513
Juno - - -	-	-	-	-	-	-	266400
Pallas - - -	1682			-	-	-	276500
Ceres - - -	1681			-	-	-	276700
Jupiter - - -	4330	8	58	4332	8	51	520110
Saturn - - -	10749	7	22	10761	14	37	953800
Uranus - - -	30456	1	41	-	-	-	1908180

As to the comets, the periods of very few of them are known. There is one however of between 75 and 76 years, which appeared for the last time in 1759; another was supposed to have its period of 129 years, which was expected to appear in 1789 or 1790, but it did not; and the comet which appeared in 1680 it is thought has its period of 575 years.

Period, in Chronology, denotes an epoch, or interval of time, by which the years are reckoned; or a series of years by which time is measured, in different nations. Such are the Calippic and Metonic Periods, two different corrections of the Greek calendar, the Julian Period, invented by Joseph Scaliger; the Victorian Petiod, &c.

Calippic Period. See Calippic *Period*.

Constantinopolitan Period, is that used by the Greeks, and is the same as the *Julian* Period, which see.

Chaldaic Period. See Saros.

Dionysian Period. See *Victorian* Period.

Hipparchus's Period, is a series or cycle of 304 solar years, returning in a constant round, and restoring the new and full moons to the same day of the solar year; as Hipparchus thought.—This period arises by multiplying the Calippic period by 4. Hipparchus assumed the quantity of the solar year to be 365^d 5^h 55^m 12^s; and hence he concluded, that in 304 years Calippus's period would err a whole day. He therefore multiplied the period by 4, and from the product cast away an entire day. But even this does not restore the new and full moons to the same day throughout the whole period: they are sometimes anticipated 1^d 8^h 23^m 29^s 20 thirds.

Julian Period, so called as being adapted to the Julian year, is a series of 7980 Julian years; arising from the multiplications of the cycles of the sun, moon, and indiction together, or the numbers 28, 19, 15; commencing on the 1st day of January in the 764th Julian year before the creation, and therefore is not yet completed. This comprehends all other cycles, periods, and epochs, with the times of all memorable actions and histories; and therefore it is not only the most general, but the most useful of all periods in chronology.

As every year of the Julian period has its particular solar, lunar, and indiction cycles, and no two years in it can have all these three cycles the same, every year of this period becomes accurately distinguished from another.—This period was invented by Joseph Scaliger, as containing all the other epochs, to facilitate the reduction of the years of one given epoch to those of another. It agrees with the Constantinopolitan period, used by the Greeks, except in this, that the cycles of the sun, moon, and indiction, are reckoned differently; and that the first year of the Constantinopolitan period differs from that of the Julian period. To find the year answering to any given year of the Julian period, and vice versa; see Epoch.

Metonic Period. See Cycle *of the Moon*.

Victorian Period, an interval of 532 Julian years; at the end of which, the new and full moons return again on the same day of the Julian year, according to the opinion of the inventor Victorinus, or Victorius, who lived in the time of pope Hilary. Some ascribe this period to Dionysius Exiguus, and hence they call it the Dionysian period: others again call it the Great Paschal Cycle, because it was invented for computing the time of Easter.

The Victorian period is produced by multiplying the solar cycle 28 by the lunar cycle 19, the product being 532. But neither does this restore the new and full moons to the same day throughout its whole duration, by 1^d 16^h 58^m 59^s 40 thirds.

Period, in Arithmetic, is a distinction made by a point, or a comma, after every 6th place, or figure; and is used in numeration, for the readier distinguishing and naming the several figures or places, which are thus distinguished into periods of six figures each. See Numeration.

Period is also used in arithmetic, in the extraction of roots, to point off, or separate the figures of the given number into periods, or parcels, of as many figures each as are expressed by the degree of the root to be extracted, viz, of two places each for the square root, three for the cube root, and so on.

PERIODIC, or Periodical, appertaining to period, or going by periods. Thus, the periodical motion of the moon, is that of her monthly period or course about the earth, called her periodical month, containing 27 days 7 hours 45 minutes.

Periodical *Month*. See Month.

PERIŒCI, or Periœcians, in Geography, are such as live in opposite points of the same parallel of latitude. Hence they have the same seasons at the same time, with the same phenomena of the heavenly bodies; but their times of the day are opposite, or differ by 12 hours, being noon with the one when it is midnight with the other.

PERIPATETIC *Philosophy*, the system of philosophy taught and established by Aristotle, and maintained by his followers, the Peripatetics. See ARISTOTLE.

PERIPATETICS, the followers of Aristotle. Though some derive their establishment from Plato himself, the master of both Xenocrates and Aristotle.

PERIPHERY, in Geometry, is the circumference, or bounding line, of a circle, ellipse, or other regular curvilineal figure. See CIRCUMFERENCE, and CIRCLE.

PERISCII, or PERISCIANS, those inhabitants of the earth, whose shadows do, in one and the same day, turn quite round to all the points of the compass, without disappearing.—Such are the inhabitants of the two frozen zones, or who live within the compass of the arctic and antarctic circles; for as the sun never sets to them, after he is once up, but moves quite round about, so do their shadows also.

PERISTYLE, in the ancient Architecture, a place or building encompassed with a row of columns on the inside; by which it is distinguished from the peripterc, where the columns are disposed on the outside.

PERISTYLE is also used, by modern writers, for a range of columns, either within or without a building.

PERITROCHIUM, in Mechanics, is a wheel or circle, concentric with the base of a cylinder, and moveable together with it, about an axis. The axis, with the wheel, and levers fixed in it to move it, make that mechanical power, called Axis *in Peritrochio*.

PERMUTATIONS *of Quantities*, in Algebra, denotes the different orders in which any quantities may be arranged; thus, the permutation of the three quantities, *a*, *b*, *c*, taken two and two together, are six; as, *ab*, *ba*, *ac*, *ca*, *bc*, *cb*; being thus distinguished from combinations, which only relate to the different collection of quantities without regard to their order, so that the combinations of the above three quantities are only three, as *ab*, *ac*, *bc*. Therefore, having found the number of combinations of any number of things, we must then find the number of permutations that any one combination will admit of, and the product of the two will be the number of permutation. Or the number of permutation (P) of any number (n) of things, taken any number (r) at a time, may be obtained from the following general formula, or theorem, $P = n \times (n-1) \times (n-2) \times (n-3) \text{ - - - - - } (n-r-1)$, while the numbers of combinations (C) of the same things, taken the same number at a time, will be represented by

$$C = \frac{n \times (n-1) \times (n-2) \times (n-3) \text{ - - - - } (n-\overline{r-1})}{1 \times 2 \times 3 \times 4 \text{ - - - - } r}.$$

From the foregoing theorem it appears, that the number of permutations or changes tnat can be made upon any number (n) of things taken together, that is, without considering them as taken a certain number at a time, as the number of changes that may be made on a given number of bells, &c, will be expressed by the continued product $n \times (n-1) \times (n-2) \times (n-3)$ &c. - - - - - $(n - n + 1)$; and thus, the number of changes that may be rung on 12 bells will be found to be expressed by the number 479001600.

When there are a certain number of things of one sort, and a certain number of another, &c, to find the number of changes that can be made out of them all.

Take the series $1 \times 2 \times 3 \times 4$ &c, up to the number of things given. Also the series $1 \times 2 \times 3$ &c, up to the number of things given of the first sort, and the same again for the number of the second sort, &c; then the first product divided by the joint products of the last series will give the answer. Or calling n the whole number of things; r, s, t, &c, the number of each sort, and P the number of permutations required, we shall have

$$P = \frac{1 \times 2 \times 3 \times 4 \times 5 \text{ - - - - - - - - } n}{(1 \times 2 \times 3 \,..\, r) \times (1 \times 2 \times 3 \,..\, s) \times (1 \times 2 \times 3 \,..\, t)}.$$

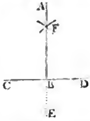
But if in this last problem, instead of supposing the permutations to take place among the number of things taken collectively, it was required to find the number of permutations of the same things, taken any given number of things at a time, the operation is more tedious; and indeed the best rule that has yet been given for it, is little better than mere trial, being as follows:—Find all the different forms of combination of all the given things, taken as many at a time as in the question; then find the number of permutations in any form, and multiply it by the number of combinations in that form. Do the same for every distinct form, and the sum of all the products will give the whole number of permutations required.

But when only the number of combinations are required as in the following question: To find the number of combinations that can be formed out of a given number of things, in which there are m things of one sort, n things of another sort, p things of another sort, &c, by taken 1 at a time, 2 at a time, &c, to any given number of things at a time. Then we have a very simple rule which was given in No. 103 of Nicholson's Philosophical Journal; as follows,

Place in a horizontal row $m + 1$ units, annexing ciphers on the right hand, till the whole number of units and ciphers exceeds the greatest number of things to be taken at a time by unity.

Under each of these terms write the sum of the $n + 1$ left-hand terms, including that as one of them, under which the number is placed; and under each of these write the sum of the $p + 1$ left-hand terms of the last line: and under each of these last the $q + 1$ left-hand terms, and so on through all the number of different things; then the last line will be the answer: that is, the second term shows the number of combinations taken 1 at a time, the third term the number of combinations taken 2 at a time, &c.

PERPENDICULAR, in Geometry, or NORMAL. One line is perpendicular to another, when the former meets the latter so as to make the angles on both sides of it equal to each other. And those angles are called right angles. And hence, to be perpendicular to, or to make right-angles with, means one and the same thing. So, when the angle ABC is equal to the angle ABD, the line AB is said to be perpendicular, or normal, or at right angles to the line CD.



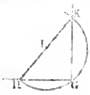
A line is perpendicular to a curve, when it is perpendicular to the tangent of the curve at the point of contact.

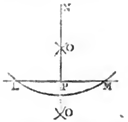
A line is perpendicular to a plane, when it is perpendicular to every line drawn in the plane through the bottom of the perpendicular. And one plane is perpendicular to another, when every line in the one plane which is perpendicular to the line of their common section, is perpendicular to the other plane.

From the very principle and notion of a perpendicular, it follows, 1. That the perpendicularity is mutual, that is, if the first AB is perpendicular to the second CD, then is the second perpendicular to the first.—2. That only one perpendicular can be drawn from one point in the same plane.—3. That if a perpendicular be continued through the line it was drawn perpendicular to; the continuation BE will also be perpendicular to the same.—4. That a line which is perpendicular to another line, is also perpendicular to all the parallels of the other.—5. That a perpendicular is the shortest of all those lines which can be drawn from the same point to the same right line. Hence the distance of a point from a line or plane, is a line drawn from the point perpendicular to the line or plane: and hence also the altitude of a figure is a perpendicular let fall from the vertex to the base.

To Erect a Perpendicular from a given point in a line. —1. When the given point B is near the middle of the line; with any interval in the compasses take the two equal parts BC, BD: and from the two centres C and D, with any radius greater than BC or BD, strike two arcs intersecting in F; then draw BFA, which will be the perpendicular required.

2. When the given point G is at or near the end of the line; with any centre I and radius IG describe an arc HGK through G; then a ruler laid by H and I will cut the arc in the point K, through which the perpendicular GK must be drawn.





To let fall a Perpendicular upon a given line LM from a given point N. With the centre N, and a convenient radius, describe an arc cutting the given line in L and M; with these two centres, and any other convenient radius, strike two other arcs intersecting in O, the point through which the perpendicular NOP must be drawn.

Perpendiculars are best drawn, in practice, by means of a square, laying one side of it along the given line, and the other to pass through the given point.

PERPENDICULAR, in Gunnery, is a small instrument used for finding the centre line of a piece, in the operation of pointing it to a given object. See *Pointing of a* GUN.

PERPETUAL *Motion.* See MOTION.

Circle of PERPETUAL *Occultation and Apparition.* See CIRCLE.

PERPETUAL, or *Endless, Screw.* See SCREW.

PERPETUITY, in the Doctrine of Annuities, is the number of years in which the simple interest of any principal sum will amount to the same as the principal itself. Or it is the quotient arising by dividing 100, or any other principal, by its interest for one year. Thus, the perpetuity, at the rate of 5 per cent. interest, is $\frac{100}{5} = 20$; at 4 per cent. $\frac{100}{4} = 25$; &c.

PERRY (Captain JOHN), was a celebrated English engineer. After acquiring great reputation for his skill in this country, he resided many years in Russia, having been recommended to the czar Peter while in England, as a person capable of serving him on a variety of occasions, relating to his new design of establishing a fleet, making his rivers navigable, &c. His salary in this service was to be 300l. per annum, besides travelling expenses and subsistence money on whatever service he should be employed, with a further reward to his satisfaction at the conclusion of any work he should finish.

After some conversation with the czar himself, particularly respecting a communication between the rivers Volga and Don, he was employed on that work for three summers successively; but not being well supplied with men, partly on account of the ill success of Peter's arms against the Swedes at the battle of Narva, and partly by the discouragement of the governor of Astracan, he was ordered at the end of 1707 to stop, and next year was employed in refitting the ships at Veronise, and in 1709 in making the river of that name navigable. But after repeated disappointments, and fruitless applications for his salary, he at length quitted the kingdom, under the protection of Mr. Whitworth, the English ambassador, in 1712. (See his Narrative in the Preface to The State of Russia.)

In 1721 he was employed in stopping the breach at Dagenham, made in the bank of the river Thames, near the village of that name in Essex, and about 3 miles below Woolwich, in which he happily succeeded, after several other persons had failed in that undertaking. He was also employed, the same year, about the harbour at Dublin, and published at that time an Answer to the objections made against it.—Besides this piece, Captain Perry was author of The State of Russia, 1716, 8vo; and An Account of the Stopping of Dagenham Breach, 1721, 8vo.—He died Feb. 11th, 1733.

PERSEUS, a constellation of the northern hemisphere, being one of the 48 ancient asterisms.—The Greeks fabled that this is Perseus, whom they make the son of Jupiter by Danae. The father of that lady had been told, that he should be killed by his grandchild, and having only Danae to take care of, he locked her up; but Jupiter found his way to her in a shower of gold, and Perseus verified the oracle. He cut off also the head of the gorgon, and affixed it to his shield; and after many other great exploits he rescued Andromeda, the daughter of Cassiopeia, whom the sea-nymphs, in revenge for that lady's boasting of superior beauty, had fastened to a rock to be devoured by a monster. Jupiter his father in honour of the exploit, they say, afterwards took up the hero, and the whole family with him, into the skies.—The number of stars in this constellation, in Ptolemy's catalogue, are 29; in Tycho's 29, in Hevelius's 46, and in the Britannic catalogue 59.

PERSIAN *Wheel*, in Mechanics, a machine for raising a quantity of water, to serve for various purposes. Such a wheel is represented in plate 25, fig. 1; with which water may be raised by means of a stream AB turning a wheel CDE, according to the order of the letters, with buckets *a, a, a, a,* &c, hung upon the wheel by strong pins *b, b, b, b,* &c, fixed in the side of the rim; which must be made as high as the water is intended to be raised above the level of that part of the stream in which the wheel is placed. As the wheel turns, the buckets on the right hand go down into the water, where they are filled, and return up full on the left hand, till they come to the top at K; where they strike against the end *n* of the fixed trough M, by which they are overset, and so empty the water into the trough; whence it is to be conveyed in pipes to any place it is intended for: and as each bucket gets over the trough, it falls into a perpendicular position again, and so goes down empty till it comes to the water at A, where it is filled as before. On each bucket is a spring *r*, which going over the top or crown of the bar *m* (fixed to the trough M) raises the bottom of the bucket above the level of its mouth, and so causes it to empty all its water into the trough.

Sometimes this wheel is made to raise water no higher than its axis; and then instead of buckets hung upon it, its spokes C, *d*, *e*, *f*, *g*, *h*, are made of a bent form, and hollow within; these hollows opening into the holes C, D, E, F, in the outside of the wheel, and also into those at O in the box N upon the axis. So that, as the holes C, D, &c, dip into the water, it runs into them; and as the wheel turns, the water rises in the hollow spokes, *c*, *d*, &c, and runs out in a stream P from the holes at O, and falls into the trough Q, whence it is conveyed by pipes.

PERSIAN, or PERSIC, in Architecture, a name common to all statues of men; serving instead of columns to support entablatures.

PERSIAN *Era* and *Year*. See EPOCH and YEAR.

PERSPECTIVE, the art of delineating visible objects on a plane surface, such as they appear at a given distance, or height, on a transparent plane, placed commonly perpendicular to the horizon, between the eye and the object. This is particularly called

Linear PERSPECTIVE, as regarding the position, magnitude, form, &c, of the several lines, or contours of objects, and expressing their diminution.

Some make this a branch of Optics; others an art and science derived from it: its operations however are all geometrical.

History of PERSPECTIVE. This art derives its origin from painting, and particularly from that branch of it which was employed in the decorations of the theatre, where landscapes were chiefly introduced. Vitruvius, in the proem to his 7th book, says that Agatharchus, at Athens, was the first author who wrote upon this subject, on occasion of a play exhibited by Æschylus, for which he prepared a tragic scene; and that afterwards the principles of the art were more distinctly taught in the writings of Democritus and Anaxagoras, the disciples of Agatharchus, which are not now extant.

The perspective of Euclid and of Heliodorus Larisseus contains only some general elements of optics, that are by no means adapted to any particular practice; though they furnish some materials that might be of service even in the linear perspective of painters.

Geminus, of Rhodes, a celebrated mathematician, in Cicero's time, also wrote upon this science. It is also evident that the Roman artists were acquainted with the rules of perspective, from the account which Pliny (Nat. Hist. lib. 35, cap. 4) gives of the representation on the scene of those plays given by Claudius Pulcher; by the appearance of which the crows were so deceived, that they endeavoured to settle on the fictitious roofs. However, of the theory of this art among the ancients we know nothing; as none of their writings have escaped the general wreck of ancient literature in the dark ages of Europe. Doubtless this art must have been lost, when painting and sculpture no longer existed. However, there is reason to believe that it was practised much later in the eastern empire.

John Tzetzes, in the 12th century, speaks of it as well acquainted with its importance in painting and statuary. And the Greek painters, who were employed by the Venetians and Florentines, in the 13th century, it seems brought some optical knowledge along with them into Italy: for the disciples of Giotto are commended for observing perspective more regularly than any of their predecessors in the art had done; and he lived in the beginning of the 14th century.

The Arabians were not ignorant of this science; as may be presumed from the optical writings of Alhazen, about the year 1100. And Vitellus, a Pole, about the year 1270, wrote largely and learnedly on optics. And, of our own nation, friar Bacon, as well as John Peckham, archbishop of Canterbury, treated this subject with great accuracy, considering the times in which they lived.

The first authors who professedly laid down rules of perspective, were Bartolomeo Bramantino, of Milan, whose book, Regole di Perspectiva, e Misure delle Antichita di Lombardia, is dated 1440; and Pietro del Borgo, likewise an Italian, who was the most ancient author met with by Ignatius Danti, and who it is supposed died in 1443. This last writer supposed objects placed beyond a transparent tablet, and so to trace the images, which rays of light, emitted from them, would make upon it. Albert Durer constructed a machine on the principles of Borgo, by which he could trace the perspective appearance of objects.

Leon Battista Alberti, in 1450, wrote his treatise De Pictura, in which he treats chiefly of perspective.

Balthazar Peruzzi, of Siena, who died in 1536, had diligently studied the writings of Borgo; and his method of perspective was published by Serlio in 1540. To him it is said we owe the discovery of points of distance, to which are drawn all lines that make an angle of 45° with the ground line.

Guido Ubaldi, another Italian, soon after discovered, that all lines that are parallel to one another, if they be inclined to the ground line, converge to some point in the horizontal line; and that through this point also will pass a line drawn from the eye parallel to them. His Perspective was printed at Pisaro in 1600, and contained the first principles of the method afterwards discovered by Dr. Brook Taylor.

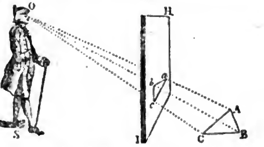
In 1583 was published the work of Giacomo Barozzi, of Vignola, entitled, The two Rules of Perspective, with a learned commentary by Ignatius Danti. In 1615 Marolois' work was printed at the Hague, and engraved and published by Hondius. And in 1625, Sirigatti published his treatise of perspective, which is little more than an abstract of Vignola's.

Since that time the art of perspective has been gradually improved by subsequent geometricians, particularly by professor Gravesande, and still more by Dr. Brook Taylor, whose principles are in a great measure new, and far more general than those of any of his predecessors. He did not confine his rules, as they had done, to the horizontal plane only, but made them general, so as to affect every species of lines and planes, whether they were parallel to the horizon or not; and thus his principles were made universal. Besides, from the simplicity of his rules, the tedious progress of drawing out plans and elevations for any object, is rendered useless, and therefore avoided; for by this method, not only the fewest lines possible are required to produce any perspective representation, but every figure thus drawn will bear the nicest mathematical examination. Further, his system is the only one calculated for answering every purpose of those who are practitioners in the art of design; for by it they may produce either the whole, or only so much of an object as is wanted; and by fixing it in its proper place, its apparent magnitude may be determined in an instant. It explains also the perspective of shadows, the reflection of objects from polished planes, and the inverse practice of perspective. His Linear Perspective was first published in 1715; and his New Principles of Linear Perspective in 1719, which he intended as an explanation of his first treatise. And his method has been chiefly followed by all others since.

In 1738 Mr. Hamilton published his Stereography, in 2 vols folio, after the manner of Dr. Taylor. But the neatest system of perspective, both as to theory and practice, on the same principles, is that of Mr. Kirby. There are also good treatises on the subject, by Desargues, Debosse, Albertus, Lamy, Niceron, Pozzo the Jesuit, Ware, Cowley, Priestley, Ferguson, Emerson, Malton, Henry Clarke, &c, &c.

Of the Principles of PERSPECTIVE. To give an idea of the first principles and nature of this art; suppose a transparent plane, as of glass, &c, HI raised perpendicularly on a horizontal plane; and the spectator S directing his eye O to the triangle ABC: if now we conceive the rays AO, BO, CO, &c, in their passage through the plane, to leave their traces or vestiges in *a*, *b*, *c*, &c, on the plane; there will appear the triangle *abc*; which, as it strikes the eye by the same rays *ao*, *bo*, *co*, by which the reflected particles of light from the triangle are transmitted to the same, it will exhibit the true appearance of the triangle ABC, though the object should be removed, the same distance and height of the eye being preserved.

The business of perspective then, is to show, by what certain rules the points *a*, *b*, *c*, &c, may be found geometrically: and hence also we have a mechanical method of delineating any object very accurately.



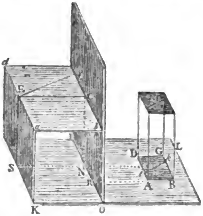
Hence it appears that *abc* is the section of the plane of the picture with the rays, which proceed from the original object to the eye: and therefore, when this is parallel to the picture, its representation will be both parallel to the original, and similar to it, though smaller in proportion as the original object is farther from the picture. When the original object is brought to coincide with the picture, the representation is equal to the original; but as the object is removed farther and farther from the picture, its image becomes smaller and smaller, and also rises higher and higher in the picture, till at last, when the object is supposed to be at an infinite distance, its image vanishes in an imaginary point, exactly as high above the bottom of the picture as the eye is above the ground plane, on which the spectator, the picture, and the original object are supposed to stand.

This may be familiarly illustrated in the following manner: Suppose a person at a window looks through an upright pane of glass at any object beyond; and, keeping his head steady, draws the figure of the object upon the glass, with a black-lead pencil, as if the point of the pencil touched the object itself; he would then have a true representation of the object in perspective; as it appears to his eye. For properly drawing on the glass, it is necessary to lay it over with strong gum water, which will be fit for drawing upon when dry, and will then retain the traces of the pencil. The person should also look through a small hole in a thin plate of metal, fixed about a foot from the glass, between it and his eye; keeping his eye close to the hole, otherwise he might shift the position of his head, and so make a false delineation of the object.

Having traced out the figure of the object, he may go over it again, with pen and ink; and when that is dry, cover it with a sheet of paper, tracing the image upon this with a pencil; then taking away the paper, and laying it upon a table, he may finish the picture, by giving it the colours, lights, and shades, as he sees them in the object itself; and thus he will have a true resemblance of the object on the paper.

Of certain Definitions in PERSPECTIVE.

The point of sight, in perspective, is the point E, where the spectator's eye should be placed to view the picture. And the *point of sight*, in the picture, called also the *centre of the picture*, is the point C directly opposite to the eye, where a perpendicular from the eye at E meets the picture. Also this perpendicular EC is the *distance of the picture:* and if this distance be transferred to the horizontal line on each side of the point C, as is sometimes done, the extremes are called the points of distance.



The *original plane*, or *geometrical plane*, is the plane KL upon which the real or original object ABGD is situated. The line OI, where the ground plane cuts the bottom of the picture, is called the *section* of the original plane, the *ground-line*, the *line of the base*, or the *fundamental line*. If an original line AB be continued, so as to intersect the picture, the point of intersection R is called the intersection of that original line, or its *intersecting point*. The *horizontal plane* is the plane *abgd*, which passes through the eye, parallel to the horizon, and cuts the perspective plane or picture at right angles; and the *horizontal line bg* is the common intersection of the horizontal plane with the picture.

The *vertical plane* is that which passes through the eye at right angles both to the ground plane and to the picture, as ECSN. And the *vertical line* is the common section of the vertical plane and the picture, as CN.

The *line of station* SN is the common section of the vertical plane with the ground plane, and perpendicular to the ground line OI.

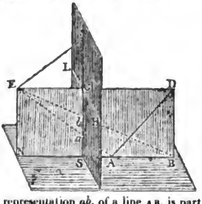
The *line of the height of the eye* is a perpendicular, as ES, let fall from the eye upon the ground plane.

The *vanishing line* of the original plane, is that line where a plane passing through the eye, parallel to the original picture, cuts the picture: thus *bg* is the vanishing line of ABGD, being the greatest height to which the image can rise, when the original object is infinitely distant.

The *vanishing point* of the original line, is that point where a line drawn from the eye, parallel to that original line, intersects the picture: thus C and *g* are the vanishing points of the lines AB and *ki*. All lines parallel to each other have the same vanishing point. If from the point of sight a line be drawn perpendicular to any vanishing line, the point where that line intersects the vanishing line, is called the centre of that vanishing line: and the *distance of a vanishing line* is the length of the line which is drawn from the eye, perpendicular to the said line.

Measuring points are points from which any lines in the perspective plane are measured, by laying a ruler from them to the divisions laid down upon the ground line. The measuring point of all lines parallel to the ground line, is either of the points of distance on the horizontal line, or point of sight. The measuring point of any line perpendicular to the ground line, is in the point of distance on the horizontal line; and the measuring point of a line oblique to the ground line is found by extending the compasses from the vanishing point of that line to the point of distance on the perpendicular, and setting off on the horizontal line.

Some general Maxims or Theorems in PERSPECTIVE.

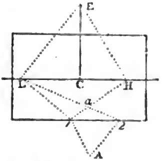


1. The representation *ab*, of a line AB, is part of a line SC, which passes through the intersecting point S, and the vanishing point C, of the original line AB.

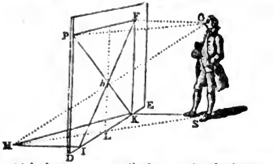
2. If the original plane be parallel to the picture, it can have no vanishing line upon it; and consequently the representation will be parallel. When the original is perpendicular to the ground line, as AB, then its vanishing point is in C, the centre of the picture, or point of sight; because EC is perpendicular to the picture, and therefore parallel to AB.

3. The image of a line bears a certain proportion to its original. And the image may be determined by transferring the length or distance of the given line to the intersecting line; and the distance of the vanishing point to the horizontal line; i. e. by bringing both into the plane of the picture.

PROB. *To find the representation of an Objective point* A.—Draw A1 and A2 at pleasure, intersecting the bottom of the picture in 1 and 2; and from the eye E draw EH parallel to A1, and EL parallel to A2; then draw H1 and L2, which will intersect each other in *a*, the representation of the point A.



Otherwise. Let H be the given objective point,



from which draw HI perpendicular to the fundamental line DE. From the fundamental line DE cut off IK = IH: through the point of sight F draw a horizontal line FP, and make FP equal to the distance of the eye SK: lastly, join FI and PK, and their intersection *h* will be the appearance of the given objective point H, as required. And thus, by finding the representations of the two points, which are the extremes of a line, and connecting them together, there will be formed the representation of the line itself. In like manner, the representations of all the lines or sides of any figure or solid, determine those of the solid itself; which therefore are thus put into perspective.

Aerial PERSPECTIVE, is the art of giving a due diminution or gradation to the strength of light, shade, and colours of objects, according to their different distances, the quantity of light which falls upon them, and the medium through which they are seen.

PERSPECTIVE *Machine*, is a machine for readily and easily making the perspective drawing and appearance of any object, which requires little or no skill in the art. There have been invented various machines of this kind. One of which may even be seen in the works of Albert Durer. A very convenient one was invented by Dr. Bevis, and is described by Mr. Ferguson, in his Perspective, pa. 113. And another is described in Kirby's Perspective, pa. 65.

PERSPECTIVE *Plan*, or *Plane*, is a glass or other transparent surface supposed to be placed between the eye and the object, and usually perpendicular to the horizon.

Scenographic PERSPECTIVE. See SCENOGRAPHY.

PERSPECTIVE *of Shadows*. See SHADOW.

Specular PERSPECTIVE, is that which represents the objects in cylindrical, conical, spherical, or other mirrors.

PERTICA, a kind of comet, the same with VERU.

PETARD, a military engine, somewhat resembling in shape a high-crowned hat; serving formerly to break down gates, barricades, draw-bridges, or the like works intended to be surprised. It is about 8 or 9 inches wide, and weighs from 55 to 70 pounds. Its use was chiefly in a clandestine or private attack, to break down the gates &c. It has also been used in countermines, to break through the enemies' galleries, and give vent to their mines: but the use of petards is now discontinued.—Their invention is ascribed to the French Hugonots in the year 1579. The most signal exploit performed with them was the taking the city Cahors, as we are told by d'Aubigné.

PETIT (PETER), a considerable mathematician and philosopher of France, was born at Montluçon in the diocese of Bourges, in the year 1589 according to some, but in 1600 according to others.—He first cultivated the mathematics and philosophy in the place of his nativity; but in 1633 he repaired to Paris, to which place his reputation had procured him an invitation. Here he became highly celebrated for his ingenious writings, and for his connections with Pascal, Descartes, Mersenne, and the other great men of that time. He was employed on several occasions by cardinal Richelieu; he was commissioned by this minister to visit the sea-ports, with the title of the king's engineer; and was also sent into Italy on the king's business. He was at Tours in 1640, where he married; and was afterwards made intendant of the fortifications. Baillet, in his Life of Descartes, says, that Petit had a great genius for mathematics; that he excelled particularly in astronomy; and had a singular passion for experimental philosophy. About 1637 he returned to Paris from Italy, when the Dioptrics of Descartes were much spoken of. He read them, and communicated his objections to Mersenne, with whom he was intimately acquainted. And yet he soon after embraced the principles of Descartes, becoming not only his friend, but his partisan and defender also. He was intimately connected with Pascal, with whom he made at Rouen the same experiments concerning the vacuum, which Torricelli had before made in Italy; and was assured of their truth by frequent repetitions. This was in 1646 and 1647; and though there appears to be a long interval from this date to the time of his death, we meet with no other memoirs of his life. He died August the 20th 1667, at Lagny, near Paris, whither he had retired for some time before his decease.

Petit was the author of several works on physical and astronomical subjects; the chief of which are,

1. Chronological Discourse, &c, 1636, 4to. In defence of Scaliger.—2. Treatise on the Proportional Compasses.—3. On the Weight and Magnitude of Metals.—4. Construction and Use of the Artillery Calipers.—5. On a vacuum.—6. On Eclipses.—7. On Remedies against the Inundations of the Seine at Paris.—8. On the Junction of the Ocean with the Mediterranean Sea, by means of the rivers Aude and Garonne.—9. On Comets.—10. On the proper day for celebrating Easter.—11. On the Nature of Heat and Cold, &c.

PETTY (Sir WILLIAM), a singular instance of a universal genius, was the elder son of Anthony Petty, a clothier at Rumsey in Hampshire, where he was born May the 16th, 1623. While a boy he took great delight in spending his time among the artificers there, whose trades he could work at when but 12 years of age. He then went to the grammar-school in that place, where at 15 he became master of the Latin, Greek, and French languages, with arithmetic and those parts of practical geometry and astronomy useful in navigation. Soon after, he went to the university of Caen in Normandy; and after some stay there he returned to England, where he was promoted in the king's navy. In 1643, when the civil war began, and the times became troublesome, he went into the Netherlands and France for three years; and having vigorously prosecuted his studies, especially in physic, at Utrecht, Leyden, Amsterdam, and Paris, he returned home to Rumsey. In 1647 he obtained a patent to teach the art of double writing for 17 years. In 1648 he published at London, "Advice to Mr. Samuel Hartlib, for the advancement of some particular parts of learning." At this time he adhered to the prevailing party of the nation; and went to Oxford, where he taught anatomy and chemistry, and was created a doctor of physic, and rose into such repute, that the philosophical meetings, which preceded and laid the foundation of the Royal Society, were first held at his house. In 1650 he was made professor of anatomy there; and soon after a member of the college of physicians in London, as also professor of music at Gresham-college, London. In 1652 he was appointed physician to the army in Ireland; as also to three lord lieutenants successively, Lambert, Fleetwood, and Henry Cromwell. After the rebellion was over in Ireland, he was appointed one of the commissioners for dividing the forfeited lands to the army who suppressed it; where he acquired a great fortune. When Henry Cromwell became lieutenant of that kingdom, in 1655, he appointed Dr. Petty his secretary, and clerk of the council: he likewise procured him to be elected a burgess for Westloo in Cornwall, in Richard Cromwell's parliament, which met in January 1658. But, in March following, Sir Hierom Sankey, member for Woodstock in Oxfordshire, impeached him of high crimes and misdemeanors in the execution of his office. This gave the doctor a great deal of trouble, as he was summoned before the house of commons; and notwithstanding the strenuous endeavours of his friends, in their recommendations of him to secretary Thurloe, and the defence he made before the house, his enemies procured his dismission from his public employments, in 1659. He then retired to Ireland, till the restoration of king Charles the Second; soon after which he came into England, where he was very graciously received by the king, resigned his professorship at Gresham-college, and was appointed one of the commissioners of the Court of Claims. Likewise, April the 11th, 1661, he received the honour of knighthood, and the grant of a new patent, constituting him surveyor-general of Ireland, and was there chosen a member of parliament.

On the incorporating of the Royal Society, he was one of the first members, and of its first council. And though he had left off the practice of physic, his name was continued as an honorary member of the college of physicians in 1663.

About this time he invented his double-bottomed ship, to sail against wind and tide, and afterwards presented a model of the vessel to the Royal Society; to whom also, in 1665, he communicated "A Discourse about the Building of Ships," containing some curious secrets in that art. But, upon trial, finding his ship failed in some respects, he at length gave up that project.

In 1666 sir William drew up a treatise, called Verbum

Sapienti, containing an account of the wealth and expenses of England, and the method of raising taxes in the most equal manner.—The same year, 1666, he suffered a considerable loss by the fire of London.—The year following he married Elizabeth, daughter of sir Hardresse Waller; and afterwards set up iron-works and pilchard-fishing, opened lead mines and a timber trade in Kerry, which turned to very good account. But all these concerns did not hinder him from the pursuit of both political and philosophical speculations, which he thought of public utility, publishing them either separately or by communication to the Royal Society, particularly on finances, taxes, political arithmetic, land carriage, guns, pumps, &c.

At the first meeting of the Philosophical Society at Dublin, on the plan of that at London, every thing was submitted to his direction: and when it was formed into a regular society, he was chosen president in Nov. 1684. On this occasion he drew up a "Catalogue of mean, vulgar, cheap, and simple Experiments," proper for the infant state of the society, and presented it to them; as he did also his Supellex Philosophica, consisting of 45 instruments requisite to carry on the design of their institution. In 1685 he made his will; in which he declares, that being then about 60, his views were fixed upon improving his lands in Ireland, and to promote the trade of iron, lead, marble, fish, and timber, which his estate was capable of. And as for studies and experiments, "I think now," says he, "to confine the same to the anatomy of the people, and political arithmetic; as also the improvement of ships, land-carriages, guns, and pumps, as of most use to mankind, not blaming the study of other men." But a few years after, all his pursuits were stopped by the effects of a gangrene in his foot, occasioned by the swelling of the gout, which put a period to his life, at his house, in Piccadilly, Westminster, Dec. 16, 1687, in the 65th year of his age. His corpse was carried to Rumsey, and there interred, near those of his parents.

Sir William Petty died possessed of a very large fortune, as appears by his will; where he makes his real estate about 6,500*l.* per annum, his personal estate about 45,000*l.* his bad and desperate debts 30,000*l.* and the demonstrable improvements of his Irish estate, 4000*l.* per annum; in all, at 6 per cent. interest, 15,000*l.* per annum. This estate came to his family, which consisted of his widow and three children, Charles, Henry, and Anne: of whom Charles was created baron of Shelbourne, in the county of Waterford in Ireland, by king William the Third; but dying without issue, was succeeded by his younger brother Henry, who was created viscount Dunkeron, in the county of Kerry, and earl of Shelbourne Feb. 11, 1718. He married the lady Arabella Boyle, sister of Charles earl of Cork, who brought him several children. He was member of parliament for Great Marlow in Buckinghamshire, and a fellow of the Royal Society: he died April 17, 1751. Anne was married to Thomas Fitzmorris, baron of Kerry and Lixnaw, and died in Ireland in 1737.

The variety of pursuits, in which Sir William Petty was engaged, shows him to have had a genius capable of any thing to which he chose to apply it: and it is very extraordinary, that a man of so active and busy a spirit could find time to write so many things, as it appears he did, by the following catalogue.

1. Advice to Mr. S. Hartlib &c; 1648, 4to.—2. A Brief of Proceedings between sir Hierom Sankey and the author &c; 1659, folio.—3. Reflections upon some persons and things in Ireland, &c; 1660, 8vo.—4. A Treatise of Taxes and Contribution, &c; 1662, 1667, 1685, 4to, all without the author's name. This last was re-published in 1690, with two other anonymous pieces, "The Privileges and Practice of Parliaments," and "The Politician Discovered;" with a new title-page, where it is said they were all written by sir William, which, as to the first, is a mistake.—5. Apparatus to the History of the Common Practice of Dyeing;" printed in Sprat's History of the Royal Society, 1667, 4to.—6. A Discourse concerning the Use of Duplicate Proportion, together with a New Hypothesis of Springing or Elastic Motions; 1674, 12mo.—7. Colloquium Davidis cum Anima sua, &c; 1679, folio.—8. The Politician Discovered, &c; 1681, 4to.—9. An Essay in Political Arithmetic; 1682, 8vo.—10. Observations upon the Dublin Bills of Mortality in 1681, &c; 1683, 8vo.—11. An Account of some Experiments relating to Land-carriage, Philos. Trans. No. 161.—12. Some Queries for examining Mineral Waters, ibid. No. 166.—13. A Catalogue of Mean, Vulgar, Cheap, and Simple Experiments, &c; ibid. No. 167.—14. Maps of Ireland, being an Actual Survey of the whole Kingdom, &c; 1685, folio.—15. An Essay concerning the Multiplication of Mankind; 1686, 8vo.—16. A further Assertion concerning the magnitude of London, vindicating it, &c; Philos. Trans. No. 185.—17. Two Essays in Political Arithmetic; 1687, 8vo.—18. Five Essays in Political Arithmetic; 1687, 8vo.—19. Observations upon London and Rome; 1687, 8vo.

His posthumous pieces are, (1) Political Arithmetic; 1690, 8vo, and 1755, with his life prefixed.—(2) The Political Anatomy of Ireland, with Verbum Sapienti, 1691, 1719.—(3) A Treatise of Naval Philosophy; 1691, 12mo.—(4) What a complete Treatise of Navigation should contain; Philos. Trans. No. 198.—(5) A Discourse of making Cloth with Sheep's Wool; in Birch's Hist. of the Roy. Soc.—(6) Supellex Philosophica; ibid.

PHANTASMAGORIA, a new optical instrument, which has within a few years afforded much entertainment by exhibiting, in theatres and other places of amusement, the representation of spectres and other figures on a transparent screen placed between the instrument and the spectators, and no light being suffered to appear, but that in which the images are enveloped, which renders the effect very singular; and this is still farther strengthened by the operator increasing or diminishing the size of the shadows at pleasure, by which the spectators, under the influence of an optical illusion, fancy that the figures are approaching or receding from them.

The first exhibition of this kind, (at least of late years,) was made by one Philidor at Vienna in 1790, and which was afterwards repeated by him at Paris in 1792 with very great success. And a similar spectacle was opened in that metropolis by M. Robertson in 1798; since which time they have become very common in all the countries of Europe. It seems however that something of a similar kind was exhibited so far back as the 17th century, being mentioned by Patin, in his "Relations Historiques," published at Amsterdam in 1695, though the instrument itself is not there described.

The phantasmagoria does not differ much in its construction from the magic lantern; indeed, it is now so constructed that it answers either purpose, the principal difference being, that in the phantasmagoria, the glass sliders on which the figures are painted, are rendered perfectly opake, except in the figures themselves, by which means all light is excluded except that in which the images are involved, and also the spectators are placed on the contrary side of the screen, which is made of some transparent thin substance, as muslin, or such like, that the figures may be seen through it: and the instrument is fixed on rollers or wheels, by which the operator can move it nearer to or farther from the screen, and thus give to the figures any size at pleasure: there are also other contrivances for giving the figures or any parts of them motion, as the arms, legs, eyes, &c, which have a very singular effect.

The greatest imperfection of this instrument is, that as the figures become smaller, which gives them the appearance of being at a greater distance, they become brighter, which is contrary to the natural order of things, as distance always decreases both the apparent magnitude and distinctness of objects. This defect however may be considerably lessened by the following construction, which is suggested by Dr. Young in his Lectures on Natural Philosophy.

The light of the lamp A (fig. 1. plate 29) is thrown by the mirror B, and the lenses C and D, on the painted slider at E, and the magnifier F forms the image on the screen at G. This lens is fixed to a slider, which may be drawn out of the principal support, or box H: and when the box is drawn back on its wheels, the rod IK lowers the point K, and by means of the rod KL adjusts the slider in such a manner, that the image is always distinctly painted on the screen G. When the box advances towards the screen, in order that the images may be diminished and appear to vanish, the support of the lens F suffers the screen M to fall and intercept a part of the light; thus taking off from the natural brightness of the object. The rod KN must be equal to KI, and the point I must be twice the focal length of the lens F, before the object, L being immediately under the focus of the lens. The screen M may have a triangular opening, so as to uncover the middle of the lens only, or the light may be intercepted in any other manner. See Dr. Young's Lectures of Natural Philosophy.

PHARON, the name of a game of chance. See Demoivre's Doctrine of Chances, pa. 77 and 105.

PHASES, in Astronomy, the various appearances, or quantities of illumination of the moon, Venus, Mercury, and the other planets, by the sun. These phases are very observable in the moon with the naked eye; by which she sometimes increases, sometimes wanes, is now bent into horns, and again appears a half-circle; at other times she is gibbous, and again a full circular face. And by help of the telescope, the like variety of phases is observed in Venus, Mars, &c. Copernicus, a little before the use of telescopes, foretold, that after-ages would find that Venus underwent all the changes of the moon; which prophecy was first fulfilled by Galileo, who, directing his telescope to Venus, observed her phases to resemble those of the moon; being sometimes full, sometimes horned, and sometimes gibbous.

PHASES *of an Eclipse.* To determine these for any time: Find the moon's place in her visible way for that moment; and from that point as a centre, with the interval of the moon's semidiameter, describe a circle: In like manner find the sun's place in the ecliptic, from which, with the semidiameter of the sun, describe another circle: the intersection of the two circles shows the phases of the eclipse, the quantity of obscuration, and the position of the cusps or horns.

PHENOMENON, or PHÆNOMENON, an appearance in physics, an extraordinary appearance in the heavens, or on earth; either discovered by observation of the celestial bodies, or by physical experiments, the cause of which is not obvious. Such are meteors, comets, uncommon appearance of stars and planets, earthquakes, &c. Such also are the effects of the magnet, phosphorus, &c.

PHILOLAUS, of Crotona, was a celebrated philosopher among the ancients. He was of the school of Pythagoras, to whom that philosopher's Golden Verses have been ascribed. He made the heavens his chief object of contemplation; and has been said to be the author of that true system of the world which Copernicus afterwards revived; but erroneously, because there is undoubted evidence that Pythagoras learned that system in Egypt. On that erroneous supposition however it was, that Bulliald placed the name of Philolaus at the head of two works, written to illustrate and confirm that system.

"He was (says Dr. Enfield, in his History of Philosophy) a disciple of Archytas, and flourished in the time of Plato. It was from him that Plato purchased the written records of the Pythagorean system, contrary to an express oath taken by the society of Pythagoreans, pledging themselves to keep secret the mysteries of their sect. It is probable that among these books were the writings of Timæus, on which Plato formed the dialogue which bore his name. Plutarch relates, that Philolaus was one of the persons who escaped from the house which was burned by Cylon, during the life of Pythagoras; but this account cannot be correct. Philolaus was contemporary with Plato, and therefore certainly not with Pythagoras. Interfering in affairs of state, he fell a sacrifice to political jealousy.

"Philolaus treated the doctrine of nature with great subtlety, but at the same time with great obscurity; referring every thing that exists to mathematical principles. He taught, that reason, improved by mathematical learning, is alone capable of judging concerning the nature of things: that the whole world consists of infinite and finite; that number subsists by itself, and is the chain by which its power sustains the eternal frame of things; that the Monad is not the sole principle of things, but that the Binary is necessary to furnish materials from which all subsequent numbers may be produced; that the world is one whole, which has a fiery centre, about which the ten celestial spheres revolve, heaven, the sun, the planets, the earth, and the moon; that the sun has a vitreous surface, whence the fire diffused through the world is reflected, rendering the mirror from which it is reflected visible; that all things are preserved in harmony by the law of necessity; and that the world is liable to destruction both by fire and by water. From this summary of the doctrine of Philolaus it appears probable that, following Timæus, whose writings he possessed, he so far departed from the Pythagorean system as to conceive two independent principles in nature, God and matter, and that it was from the same source that Plato derived his doctrine upon this subject."

PHILOSOPHER, a person well versed in philosophy; or who makes a profession of, or applies himself to, the study of nature or of morality.

PHILOSOPHER'S *Stone*, a long-sought-for preparation, which was to transmute or exalt impure metals, such as tin, lead, copper, &c, into gold. There are three methods by which the alchemists have attempted to arrive at the art of making gold; the first by separation, the second by maturation, and the third by transmutation, or turning all metals readily into pure gold, by melting them in the fire, and casting a little quantity of a certain preparation into the fused matter, upon which the fæces are volatilized and burnt, and the rest of the mass turned into pure gold. Many thousands of receipts have been given for conducting the experiments in this art, and many persons have ruined their fortunes in the pursuit of it; but repeated failures have at last put an end to this hopeless speculation.

PHILOSOPHICAL TRANSACTIONS, those of the Royal Society. See TRANSACTIONS.

PHILOSOPHIZING, the act of considering some object of our knowledge, examining its properties, with the phenomena it exhibits, and inquiring into their causes or effects, and the laws of them; the whole conducted according to the nature and reason of things, and directed to the improvement of knowledge.

The Rules of PHILOSOPHIZING, as established by sir Isaac Newton, are, 1. That no more causes of a natural effect be admitted than are true, and suffice to account for its phenomena. This agrees with the sentiments of most philosophers, who hold that nature does nothing in vain; and that it were vain to do that by many means, which might be done by fewer.

2. That natural effects of the same kind, proceed from the same causes. Thus, for instance, the cause of respiration is one and the same in man and brute; the cause of the descent of a stone, the same in Europe as in America; the cause of light, the same in the sun and in culinary fire; and the cause of reflection, the same in the planets as the earth.

3. Those qualities of bodies which are not capable of being heightened, and remitted, and which are found in all bodies on which experiments can be made, must be considered as universal qualities of all bodies. Thus, the extension of body is only perceived by our senses, nor is it perceivable in all bodies: but since it is found in all that we have perception of, it may be affirmed of all. So we find that several bodies are hard; and argue that the hardness of the whole only arises from the hardness of the parts: whence we infer that the particles, not only of those bodies which are sensible, but of all others, are likewise hard. Lastly, if all the bodies about the earth gravitate towards the earth, and this according to the quantity of matter in each; and if the moon gravitate towards the earth also, according to its quantity of matter; and the sea again gravitate towards the moon; and all the planets and comets gravitate towards each other: it may be affirmed universally, that all bodies in the creation gravitate towards each other. This rule is the foundation of all natural philosophy.

PHILOSOPHY, the knowledge or study of nature or morality, founded on reason and experience. Literally and originally, the word signified a love of wisdom. But by philosophy is now meant the knowledge of the nature and reasons of things; as distinguished from history, which is the bare knowledge of facts; and from mathematics, which is the knowledge of the quantity and measures of things. These three kinds of knowledge ought to be joined as much as possible. History furnishes matter, principles, and practical examinations; and mathematics completes the evidence.

Philosophy being the knowledge of the reasons of things, all arts must have their peculiar philosophy which constitutes their theory: not only law and physic, but the lowest and most abject arts are not without their reasons. It is to be observed that the bare intelligence and memory of philosophical propositions, without any ability to demonstrate them, is not philosophy, but history only. However, where such propositions are determinate and true, they may be usefully applied in practice, even by those who are ignorant of their demonstrations. Of this we see daily instances in the rules of arithmetic, practical geometry, and navigation; the reasons of which are often not understood by those who practise them with success. And this success in the application produces a conviction of mind, which is a kind of medium between philosophical or scientific knowledge, and that which is historical only.

If we consider the difference there is between natural philosophers, and other men, with regard to their knowledge of phenomena, we shall find it consists not in an exacter knowledge of the efficient cause that produces them, for that can be no other than the will of the Deity; but only in a greater and more enlarged comprehension, by which analogies, harmonies, and agreements are described in the works of nature, and the particular effects explained; that is, reduced to general rules, which rules, grounded on the analogy and uniformness observed in the production of natural effects, are more agreeable, and sought after by the mind; for that they extend our prospect beyond what is present, and near to us, and enable us to make very probable conjectures, concerning things that may have happened at very great distances of time and place, as well as to predict things to come; which sort of endeavour towards omniscience is much affected by the mind. Berkeley, Princip. of Hum. Knowledge, sect. 104, 105.

From the first broachers of new opinions, and the first founders of schools, philosophy is become divided into several sects, some ancient, others modern; such are the Platonists, Peripatetics, Epicureans, Stoics, Pyrrhonians, and Academics; also the Cartesians, Newtonians, &c. See the particular articles for each. Philosophy may be divided into two branches, or it may be considered under two circumstances, theoretical and practical.

Theoretical or *Speculative* PHILOSOPHY, is employed in mere contemplation. Such is physics, which is a bare contemplation of nature, and natural things.

Philosophy may be divided into three parts; intellectual, moral, and physical: the intellectual part comprises logic and metaphysics; the moral part contains the laws of nature and nations, ethics and politics; and lastly the physical part comprehends the doctrine of bodies, animate or inanimate: these, with their various subdivisions, will comprise the whole of philosophy.

Practical PHILOSOPHY, is that which lays down the rules of a virtuous and happy life; and excites us to the practice of them. Most authors divide it into two kinds, answerable to the two sorts of human actions to be directed by it; viz, logic, which governs the operations of the understanding; and ethics, properly so called, which direct those of the will.

For the several particular kinds of philosophy, see the articles, Arabian, Aristotelian, Atomical, Cartesian, Corpuscular, Epicurean, Experimental, Hermetical, Leibnitzian, Mechanical, Moral, Natural, Newtonian, Oriental, Platonic, Scholastic, Socratic, &c, &c.

PHLOGISTON, in Chemistry, a term that seems to be almost banished from our language. It was invented by Stahl, according to whom there is only one substance in nature capable of combustion, this he called phlogiston, and all those bodies which can be inflamed contain more or less of it. Combustion by his theory is merely the separation of this substance. Those bodies which contain some of it are incombustibles. All combustibles are composed of an incombustible body and phlogiston united; and during the combustion the phlogiston flies off, and the incombustible body is left behind. Thus when sulphur is burnt, the substance that remains is sulphuric acid, an incombustible body. Sulphur therefore is said to be composed of sulphuric acid and phlogiston. This theory has long since given place to that established by Lavoisier, and so much improved by Dr. Thomson of Edinburgh. See the article COMBUSTION.

PHŒNIX, a constellation of the southern hemisphere; being one of the new-added asterisms, unknown to the ancients, and is not visible in our northern parts of the globe. There are 13 stars in this constellation.

PHONICS, otherwise called ACOUSTICS, is the doctrine or science of sounds. Phonics may be considered as an art analogous to optics; and may be divided, like that, into direct, refracted, and reflected. These branches, the bishop of Ferns, in allusion to the parts of optics, denominates phonics, diaphonics, and cataphonics. See ACOUSTICS.

PHOSPHORUS, a matter which shines, or even burns spontaneously, and without the application of any sensible fire. Phosphori are either natural or artificial.

Natural PHOSPHORI, are matters which become luminous at certain times, without the assistance of any art or preparation. Such are the glow-worms, frequent in our colder countries; lantern-flies, and other shining insects, in hot countries; rotten-wood; the eyes, blood, scales, flesh, sweat, feathers, &c, of several animals; diamonds, when rubbed after a certain manner, or after having been exposed to the sun or light; sugar and sulphur, when pounded in a dark place; sea-water, and some mineral waters, when briskly agitated; a cat's or horse's back, duly rubbed with the hand, &c, in the dark; nay Dr. Croon tells us, that on rubbing his own body briskly with a well-warmed shirt, he has frequently made both to shine; and Dr. Sloane adds, that he knew a gentleman of Bristol, and his son, both whose stockings would shine much after walking. All natural phosphori have this in common, that they do not shine always, and that they never give any heat. Of all the natural phosphori, that which has occasioned the greatest speculation, is the

Barometrical or *Mercurial* PHOSPHORUS. M. Picard first observed, that the mercury of his barometer, when shaken in a dark place, emitted light. And many fanciful explanations have been given of this phenomenon, which however is now found to be a mere electrical effect. Mr. Hawksbee has several experiments on this appearance. Passing air forcibly through the body of quicksilver, placed in an exhausted receiver, the parts were violently driven against the side of the receiver, and gave all around the appearance of fire; continuing thus till the receiver was half full again of air.

From other experiments he found, that though the appearance of light was not producible by agitating the mercury in the same manner in the common air, yet that a very fine medium, nearly approaching to a vacuum, was not at all necessary. And lastly, from other experiments he found that mercury inclosed in water, which communicated with the open air, by a violent shaking of the vessel in which it was inclosed, emitted particles of light in great plenty, like little stars. By including the vessel of mercury, &c, in a receiver, and exhausting the air, the phenomenon was changed; and on shaking the vessel, instead of sparks of light, the whole mass appeared one continued circle of light.

Further, if mercury be inclosed in a glass tube, close stopped, that tube is found, on being rubbed, to give much more light, than when it had no mercury in it. When this tube has been rubbed, after raising successively its extremities, that the mercury might flow from one end to the other, a light is seen creeping in a serpentine manner all along the tube, the mercury being all luminous. By making the mercury run along the tube afterwards without rubbing it, it emitted some light, though much less than before; this proves that the friction of the mercury against the glass, in running along, does in some measure electrify the glass, as the rubbing it with the hand does, only in a much less degree. This is more plainly proved by laying some very light down near the tube, for this will be attracted by the electricity raised by the running of the mercury, and will rise to that part of the glass along which the mercury runs; from which it is evident, that what has been long known in the world under the name of the phosphorus of the barometer, is not a phosphorus, but merely a light raised by electricity, the mercury electrifying the tube. Philos. Trans. No. 484.

Artificial PHOSPHORI, are such as owe their luminous quality to some art or preparation. Some of these are made by the maceration of plants alone, and without any fire; such as thread, linen cloth, but above all paper: the luminous appearance of this last, which it is now known is an electrical phenomenon, is greatly increased by heat. Almost all bodies, by a proper treatment, have that power of shining in the dark, which at first was supposed to be the property of one, and afterwards only of a few. See Philos. Trans. No. 478, in vol. 44, pa. 83.

The discovery of phosphorus was made in 1677 by one Brandt, a citizen of Hamburgh, in his researches for the philosopher's stone, and the preparation was long kept a lucrative secret in the hands of a few persons; but as it was generally known to have been prepared from human urine, and as the method then employed, though tedious and disgusting, was extremely simple, it was detected by several chemists, but first by Kunckel and Mr. Boyle, and the real nature of phosphorus has been gradually explained by a vast number of ingenious and elaborate researches. Kunckel having first discovered the method of preparing this substance, it is generally called Kunckel's phosphorus.

The earliest method of preparing phosphorus was in the following manner. A large quantity of human urine was collected, and after remaining for a time to become putrid, it was evaporated to dryness in any suitable vessel. The residue was then mixed with charcoal in powder, and heated gradually to low redness in an iron pot, till the mass began to send forth blue luminous vapours. It was then removed into a coated earthen retort with a receiver, and heat applied gradually till it reached the utmost intensity; during which the phosphorus distilled over, and partly concreted in the neck of the retort, and partly fell in drops into the receiver. This, which was at first black and foul, was purified by melting, and was formed into sticks, which were long sold at a very high price, as a great philosophical curiosity.

This disgusting process is now completely laid aside, and phosphorus is obtained in a much more certain manner, from the white earth left after the calcination of bones; but for the process of which operation we must refer the reader to Murray's and Parkinson's Chemistries, and to the article Phosphorus in Aikin's Chemical Dictionary.

Many curious and amusing experiments are made with phosphorus; as by writing with it, when the letters will appear like flame in the dark, though in the light nothing appears but a dim smoke; also a little bit of it rubbed between two papers, presently takes fire, and burns vehemently; &c. By washing the face, or hands, &c, with liquid phosphorus, they will shine very considerably in the dark, and the lustre will be communicated to adjacent objects, yet, without hurting the skin: and on bringing in the candle, the shining disappears, and no change is perceivable.

PHOSPHORUS, in Astronomy, is the morning star, or the planet Venus, when she rises before the sun. The Latins call it Lucifer, the French Etoile de berger, and the Greeks Phosphorus.

PHOSPHURETS, in Chemistry, are substances formed by an union with phosphorus: thus, we have the phosphuret of carbon, which is a compound of carbon with phosphorus; we have likewise the phosphuret of lime, hydrogen, &c.

PHOSPHURETTED *Hydrogen*, phosphorus dissolved in hydrogen gas; which may be done by introducing phosphorus into a glass jar of hydrogen gas standing over mercury, and then melting it by means of a burning glass; the gas dissolves a large proportion of it. The compound has a very fetid odour, something like that from putrid fish. When it comes into contact with common air, it burns with great rapidity, and if mixed with that air it detonates violently. Oxygen gas produces a still more rapid and brilliant combustion than common air. When bubbles of it are made to pass up through water, they explode in succession as they reach the surface of the liquid; a beautiful column of white smoke is formed. This gas is the most combustible substance known. Its combustion is the combination of its phosphorus and hydrogen with the oxygen of the atmosphere, and the products are phosphoric acid and water. These substances, mixed or combined, constitute the white smoke.

PHYSICAL. Something belonging to nature, or existing in it. Thus, we say a physical point, in opposition to a mathematical one, which last only exists in the imagination. Or a physical substance or body, in opposition to spirit, or metaphysical substance, &c.

PHYSICAL, or *Sensible Horizon*. See HORIZON.

PHYSICO-*Mathematics*, or *Mixed Mathematics*, includes those branches of physics which, uniting observation and experiment to mathematical calculation, explain mathematically the phenomena of nature.

PHYSICS, called also *Physiology*, and *Natural Philosophy*, is the doctrine of natural bodies, their phenomena, causes, and effects, with their various affections, motions, operations, &c. So that the immediate and proper objects of physics, are body, space, and motion. The origin of physics is referred, by the Greeks, to the Barbarians, viz, the brachmans, the magi, and the Hebrew and Egyptian priests. From these it passed to the Greek sages or sophi, particularly to Thales, who it is said first professed the study of nature in Greece. Hence it descended into the schools of the Pythagoreans, the Platonists, and the Peripatetics; whence it passed into Italy, and thence through the rest of Europe: though the druids, bards, &c, had a kind of system of physics of their own.—Physics may be divided, with regard to the manner in which it has been treated, into the following kinds.

Symbolical PHYSICS, or such as was couched under symbols: such was that of the old Egyptians, Pythagoreans, and Platonists; who delivered the properties of natural bodies under arithmetical and geometrical characters, and hieroglyphics.

Peripatetical PHYSICS, or that of the Aristotelians, who explained the nature of things by matter, form, and privation, elementary and occult qualities, sympathies, antipathies, attractions, &c.

Experimental PHYSICS, which inquires into the reasons and natures of things from experiments: such as those in chemistry, hydrostatics, pneumatics, optics, &c.

Mechanical or *Corpuscular* PHYSICS, which explains the appearances of nature from the matter, motion, structure, and figure of bodies and their parts; all according to the settled laws of nature and mechanics. See each of these articles under its proper head.

PIASTER, a Spanish money, more usually called Piece of Eight, about the value of 4*s.* 6*d.*

PIAZZA, popularly called Piache, an Italian name for a portico, or covered walk, supported by arches.

PIAZZI, a small new primary planet, discovered Jan. 1, 1800, by the astronomer Piazzi of Palermo. It is also called CERES; which see.

PICARD (JOHN,) an able mathematician of France, and one of the most learned astronomers of the 17th century, was born at Fleche, and became priest and prior of Rille in Anjou. Coming afterwards to Paris, his talents for mathematics and astronomy soon made him known and respected. In 1666 he was appointed astronomer in the Academy of Sciences. And five years after, he was sent, by order of the king, to the castle of Uraniburg, built by Tycho Brahé in Denmark, to make astronomical observations there, and from thence he brought the original manuscripts, written by Tycho Brahé; which are the more valuable, as they differ in many places from the printed copies, and contain a book more than has yet appeared. These discoveries were followed by many others, particularly in astronomy. He was one of the first, who applied the telescope to astronomical quadrants: he first executed the work called, La Connoissance des Temps, which he calculated from 1679 to 1683 inclusively: he first observed the light in the vacuum of the barometer, or the mercurial phosphorus: he also first of any went through several parts of France, to measure the degrees of the French meridian, and first gave a chart of the country, which the Cassinis afterwards carried to a great degree of perfection. He died in 1682 or 1683, leaving a name dear to his friends, and respectable to his contemporaries and to posterity. His works are,

1. A treatise on Levelling.
2. Practical Dialling by calculation.
3. Fragments of Dioptrics.
4. Experiments on Running Water.
5. Of Measurements.
6. Mensuration of Fluids and Solids.

7. Abridgment of the Measure of the Earth.

8. Journey to Uranibuig, or Astronomical Observations made in Denmark.

9. Astronomical Observations made in France.

10. La Connoissance des Temps, from 1679 to 1683.

All these, and some other of his works, which are much esteemed, are given in the 6th and 7th volumes of the Memoirs of the Academy of Sciences.

PICKET, *Picquet*, or *Piquet*, in Fortification &c, a stake sharp at one end, and usually shod with iron, used in laying out ground, to mark its several bounds and angles. There are also larger pickets, driven into the earth, to hold together fascines or faggots, in works that are thrown up in haste. As also various kinds of smaller pickets for divers other uses.

PIECES, in Artillery, include all kinds of great guns and mortars; meaning pieces of ordnance, or of artillery.

PIEDOUCHE, in Architecture, a little stand, or pedestal, either oblong or square, enriched with mouldings; serving to support a bust, or other little figure; and is more usually called a bracket pedestal.

PIEDROIT, in Architecture, a kind of square pillar, or pier, partly hid within a wall. Differing from the pilaster by having no regular base nor capital.

PIEDROIT is also used for a part of the solid wall annexed to a door or window; comprehending the door-post, chambranle, tableau, leaf, &c.

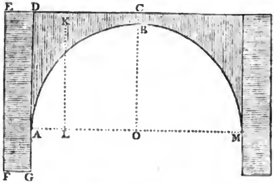
PIER, in Building, denotes a mass of stone, &c, opposed by way of fortress, against the force of the sea, or a great river, for the security of ships lying in any harbour or haven. Such are the piers at Dover, or Ramsgate, or Yarmouth, &c.

PIERS are also used in Architecture for a kind of pilasters, or buttresses, raised for support, strength, and sometimes for ornament.

Circular PIERS, are called Massive Columns, and are either with or without caps. These are often seen in Saracenic architecture.

PIERS, of a Bridge, are the walls built to support the arches, and from which they spring as bases, to stand upon. Piers should be built of large blocks of stone, solid throughout, and cramped together with iron, which will make the whole as one solid stone. Their extremities, or ends, from the bottom, or base, up to high-water mark, ought to project sharp out with a saliant angle, to divide the stream. Or perhaps the bottom part of the pier should be built flat or square up to about half the height of low-water mark, to encourage a lodgment against it for the sand and mud, to cover the foundation; lest, being left bare, the water should in time undermine and ruin it. The best form of the projection for dividing the stream, is the triangle; and the longer it is, or the more acute the saliant angle, the better it will divide it, and the less will the force of the water be against the pier; but it may be sufficient to make that angle a right one, as it will render the masonry stronger, and in that case the perpendicular projection will be equal to half the breadth or thickness of the pier. In rivers where large heavy craft navigate, and pass the arches, it may perhaps be better to make the ends semicircular; for though this figure does not divide the water so well as the triangle, it will better turn off, and bear the shock of the craft.

The thickness of the piers ought to be such as will make them of weight, or strength, sufficient to support their interjacent arch, independent of the assistance of any other arches. And then, if the middle of the pier be run up to its full height, the centring may be struck, to be used in another arch, before the hanches or spandrels are filled up. They ought also to be made with a broad bottom on the foundation, and gradually diminished in thickness by offsets up to low-water mark.



To find the thickness FG *of the Piers*, necessary to support an arch ABM, this is a general rule. Let K be the centre of gravity of the half arch ADCB, A = its area; KL perpendicular to AM the span of the arch, OB its height, and BC its thickness at the crown: then is the thickness of the pier $FG = \sqrt{(\frac{GA \times AL}{EF \times KL} \times 2A)}$.

The investigations of this rule, and other methods for this purpose, may be seen in my Tracts, vol. 1, pa. 72, &c.

PIKE, an offensive weapon, consisting of a shaft of wood, 12 or 14 feet long, headed with a flat-pointed steel, called the spear. Pliny says the Lacedemonians were the inventors of the pike. The Macedonian phalanx was evidently a battalion of pikemen. The pike was long used by the infantry, to enable them to sustain the attack of the cavalry; but it is now taken from them, and the bayonet, fixed to the muzzle of the firelock, is given instead of it. It is still used by some officers of infantry, under the name of spontoon.

Half PIKE is the weapon carried by an officer of foot; being only 8 or 9 feet long.

PILASTER, in Architecture, a square column, sometimes insulated, but more frequently let within a wall, and only projecting by a 4th or 5th part of its thickness. The pilaster is different in the different orders; borrowing the name of each order, and having the same proportions, and the same capitals, members, and ornaments, with the columns themselves.

Demi PILASTER, called also *Membretto*, is a pilaster that supports an arch; and it generally stands against a pier or column.

PILES, in Building, are large stakes, or beams, sharpened at the end, and shod with iron, to be driven into the ground, for a foundation to build upon in marshy places. Amsterdam, and some other cities, are wholly built upon piles. The stoppage of Dagenham-breach was effected by dove-tail piles, that is by piles mortised into one another by a dovetail joint. Piles are driven down by blows of a large iron weight, ram, or hammer, dropped continually upon them from a height, till the pile is sunk deep enough into the ground.

Notwithstanding the momentum, or force of a body in motion, is as the weight multiplied by the velocity, or simply as its velocity, the weight being given, or constant; yet the effect of the blow will be nearly as the square of that velocity, the effect being the quantity the pile sinks in the ground by the stroke. For the force of the blow, which is transferred to the pile, being destroyed, in some certain definite time, by the friction of the part which is within the earth, and which is nearly a constant quantity; and the spaces, in constant forces, being as the squares of the velocities; therefore the effects, which are those spaces sunk, are nearly as the square of the velocities; or, which is the same thing, nearly as the heights fallen by the ram or hammer, to the head of the pile. See, upon this subject, Leopold Belidor, also Desaguliers's Exper. Philos. vol. 1, pa. 336, and vol. 2, pa. 417: and Philos. Trans. 1779, pa. 120: also my Tracts, vol. 3, prob. 2, pa. 317.

There have been various contrivances for raising and dropping the hammer, for driving down the piles; some simple and moved by strength of men, and some complex and by machinery; but the completest pile-driver is esteemed that which was employed in driving the piles in the foundation of Westminster bridge. This machine was the invention of Mr. Vauloue, and the description of it is as follows.

Description of Vauloue's PILE-*Driver*. See fig. 2, pl. 25. A is the great upright shaft or axle, carrying the great wheel B and drum C, and turned by horses attached to the bars S, S. The wheel B turns the trundle X, having a fly O at the top, to regulate the motion, and to act against the horses, and keep them from falling when the heavy ram Q is disengaged to drive the pile P down into the mud &c, in the bottom of the river. The drum C is loose upon the shaft A, but is locked to the wheel B by the bolt Y. On this drum the great rope HH is wound; one end of it being fixed to the drum, and the other to the follower G, passing over the pulleys I and K. In the follower G are contained the tongs F, which take hold of the ram Q, by the staple R for drawing it up. D is a spiral or fusee fixed to the drum, on which winds the small rope T, which goes over the pulley U, under the pulley V, and is fastened to the top of the frame at 7. To the pulley-block V is hung the counterpoise W, which hinders the follower from accelerating as it goes down to take hold of the ram: for, as the follower tends to acquire velocity in its descent, the line T winds downwards upon the fusee, on a larger and larger radius, by which means the counterpoise W acts stronger and stronger against it; and so allows it to come down with only a moderate and uniform velocity. The bolt Y locks the drum to the great wheel, being pushed upward by the small lever 2, which goes through a mortise in the shaft A, turns upon a pin in the bar 3 fixed into the great wheel B, and has a weight 4, which always tends to push up the bolt Y through the wheel into the drum. L is the great lever turning on the axis *m*, and resting upon the forcing bar 5, 5, which goes down through a hollow in the shaft A, and bears upon the little lever 2.

By the horses going round, the great rope H is wound about the drum C, and the ram Q is drawn up by the tongs F in the follower G, till they come between the inclined planes E; which, by shutting the tongs at the top, open them below, and so discharge the ram, which falls down between the guide posts *bb* upon the pile P, and drives it by a few strokes as far into the ground as it can go, or as is desired; after which, the top part is sawed off close to the mud, by an engine for that purpose. Immediately after the ram is discharged, the piece 6 upon the follower G takes hold of the ropes *aa*, which raise the end of the lever L, and cause its end N to descend and press down the forcing bar 5 upon the little lever 2, which, by drawing down the bolt Y, unlocks the drum C from the great wheel B; and then the follower, being at liberty, comes down by its own weight to the ram; and the lower ends of the tongs slip over the staple R, and the weight of their heads causes them to fall outward, and shut upon it. Then the weight 4 pushes up the bolt Y into the drum, which locks it to the great wheel, and so the ram is drawn up as before.

As the follower comes down, it causes the drum to turn backward, and unwinds the rope from it, while the horses, the great wheel, trundle, and fly, go on with an uninterrupted motion: and as the drum is turning backward, the counterpoise W is drawn up, and its rope T wound upon the spiral fusee D. There are several holes in the under side of the drum, and the bolt Y always takes the first one that it finds when the drum stops by the falling of the follower upon the ram; till which stoppage, the bolt has not time to slip into any of the holes.

The peculiar advantages of this engine are, that the weight, called the ram, or hammer, may be raised with the least force; that, when it is raised to a proper height, it readily disengages itself and falls with the utmost freedom; that the forceps or tongs are lowered down speedily, and instantly of themselves again lay hold of the ram, and lift it up; on which account this machine will drive the greatest number of piles in the least time, and with the fewest labourers.

This engine was placed upon a barge on the water, and so was easily conveyed to any place desired. The ram was a ton weight; and the guides *b*, *b*, by which it was let fall, were 30 feet high.

A new machine for driving piles has been invented lately by Mr. S. Bunce of Kirby-street, Hatton-street, London. This, it is said, will drive a greater number of piles in a given time than any other; and that it can be constructed more simply to work by horses than Vauloue's engine above described.

Fig. 3 and 4, plate 25, represent a side and front section of the machine. The chief parts are, A, fig. 3, which are two endless ropes or chains, connected by cross pieces of iron B (fig. 4) corresponding with two cross grooves cut diametrically opposite in the wheel C (fig. 3) into which they are received; and by which means the rope or chain A is carried round. FHK is a side-view of a strong wooden frame moveable on the axis H. D is a wheel, over which the chain passes and turns within at the top of the frame. It moves occasionally from F to G upon the centre H, and is kept in the position F by the weight I fixed to the end K. In fig. 5, L is the iron ram, which is connected with the cross pieces by the hook M. N is a cylindrical piece of wood suspended at the hook at O, which by sliding freely upon the bar that connects the hook to the ram, always brings the hook upright upon the chain when at the bottom of the machine, in the position of OP. See fig. 3.

When the man at S turns the usual crane-work, the ram being connected to the chain, and passing between the guides, it is drawn up in a perpendicular direction; and when it is near the top of the machine, the projecting bar Q of the hook strikes against a cross piece of wood at R (fig. 3); and consequently discharges the ram, while the weight I of the moveable frame instantly draws the upper wheel into the position shown at F, and keeps the chain free of the ram in its descent. The hook, while descending, is prevented from catching the chain by the wooden piece N: for that piece being specifically lighter than the iron weight below, and moving with a less degree of velocity, cannot come into contact with the iron, till it is at the bottom, and the ram stops. It then falls, and again connects the hook with the chain, which draws up the ram, as before.

Mr. Bunce has made a model of this machine, which performs perfectly well: and he observes, that, as the motion of the wheel C is uninterrupted, there appears to be the least possible time lost in the operation.

PILE is also used among Architects, for a mass or body of building.

PILE, in Artillery, denotes a collection or heap of shot or shells, piled up by horizontal courses into either a pyramidal or else a wedge-like form; the base being an equilateral triangle, a square, or a rectangle. In the triangle and square, the pile terminates in a single ball or point, and forms a pyramid, as in plate 24, fig. 4 and 5, but with the rectangular base, it finishes at top in a row of balls, or an edge, forming a wedge, as in fig. 6.

In the triangular and square piles, the number of horizontal rows, or courses, or the number counted on one of the angles from the bottom to the top, is always equal to the number counted on one side, in the bottom row. And in rectangular piles, the number of rows, or courses, is equal to the number of balls in the breadth of the bottom row, or shorter side of the base: also, in this case, the number in the top row, or edge, is one more than the difference between the length and breadth of the base. All which is evident from the inspection of the figures, as above.

The courses in these piles are figurate numbers.

In a triangular pile, each horizontal course is a triangular number, produced by taking the successive sums of the ordinate numbers, viz,

$$1 = 1$$
$$1 + 2 = 3$$
$$1 + 2 + 3 = 6$$
$$1 + 2 + 3 + 4 = 10, \&c.$$

And the number of shot in the triangular pile, is the sum of all these triangular numbers, taken as far, or to as many terms, as the number in one side of the base. Therefore, to find this sum, or the number of all the shot in the pile, multiply continually together, the number in one side of the base row, and that number increased by 1, and the same number increased by 2; then $\frac{1}{6}$ of the last product will be the answer, or number of all the shot in the pile. That is, $\frac{1}{6} n . \overline{n+1} . \overline{n+2}$ is the sum; where n is the number in the bottom row.

Again, in square piles, each horizontal course is a square number, produced by taking the square of the number in its side, or the successive sums of the odd numbers, thus,

$$1 = 1$$
$$1 + 3 = 4$$
$$1 + 3 + 5 = 9$$
$$1 + 3 + 5 + 7 = 16, \&c.$$

And the number of shot in the square pile is the sum of all these square numbers, continued so far, or to as many terms, as the number in one side of the base. Therefore, to find this sum, multiply continually together, the number in one side of the bottom course, and that number increased by 1; and double the same number increased by 1; then $\frac{1}{6}$ of the last product will be the sum or answer. That is, $\frac{1}{6}n . \overline{n+1} . \overline{2n+1}$ is the sum.

In a rectangular pile, each horizontal course is a rectangle, whose two sides have always the same difference as those of the base course, and the breadth of the top row, or edge, being only 1: because each course in ascending has its length and breadth always less by 1 than the course next below it. And these rectangular courses are found by multiplying successively the terms or breadths 1, 2, 3, 4, &c, by the same terms added to the constant difference of the two sides d; thus,

$$1 . \overline{1+d} = 1 + d$$
$$2 . \overline{2+d} = 4 + 2d$$
$$3 . \overline{3+d} = 9 + 3d$$
$$4 . \overline{4+d} = 16 + 4d, \&c.$$

And the number of shot in the rectangular pile is the sum of all these rectangles, which evidently consist of the sum of the squares, together with the sum of an arithmetical progression, continued till the number of terms be the difference between the length and breadth of the base, and 1 less than the edge or top row. Therefore, to find this sum, multiply continually together, the number in the breadth of the base row, the same number increased by 1, and double the same number increased by 1, and also increased by triple the difference between the length and breadth of the base; then $\frac{1}{6}$ of the last product will be the answer. That is, $\frac{1}{6}b . \overline{b+1} . \overline{2b+3d+1}$ is the sum: where b is the breadth of the base, and d the difference between the length and breadth of the bottom course.

As to incomplete piles, which are only frustums, as wanting a similar small pile at the top; it is evident that the number in them will be found, by first computing the number in the whole pile, as if it were complete, and also the number in the small pile wanting at top, both by their proper rule; then subtracting the one number from the other.

In piling of shot, when room is an object, it may be observed that the square pile is the least eligible of any, as it takes up more room, in proportion to the number of shot contained in it, than either of the other two forms; and that the rectangular pile is the most eligible, as taking up the least room in proportion to the number it contains.

PILLAR, a kind of irregular column, round, and insulated, or detached from the wall. Pillars are not restricted to any rules, their parts and proportions being arbitrary; such for example as those that support Saracenic vaults, and other buildings, &c.

PINGRE' (ALEXANDER GUY), a French astronomer, was born at Paris in 1711; and died in 1796, at 85 years of age. He applied with great assiduity to scientific pursuits, and became librarian of St. Geneviève at Paris. In 1760 he was sent to the South sea, to observe the approaching transit of Venus over the sun's disk. He was afterwards employed in proving the going of the timepieces of M. Leroy. He was first admitted a member of the Academy of Sciences; and afterwards of the National Institute. M. Pingré's works chiefly are; 1. State of the Heavens from 1754 to 1757. 2. Memoirs of Discoveries made in the South sea, 4to. 3. Historical and Theoretical Treatise on Comets, 2 vols. 4to. 4. Translation of Manilius's Astronomics, 8vo. 5 History of Astronomy in the 17th century.

PINION, in Mechanics, is an arbor, or spindle, in the body of which are several notches, which are catched by the teeth of a wheel that serves to turn it round. Or a pinion is any lesser wheel that plays in the teeth of a larger.

In a watch, &c, the notches of a pinion are called leaves, and not teeth, as in other wheels; and their number is commonly 4, 5, 6, 8, &c.

PINION *of Report*, is that pinion, in a watch, commonly fixed on the arbor of a great wheel; and which used to have but four leaves in old watches: it drives the dial-wheel, and carries about the hand. The number of turns to be laid upon the pinion of report, is found by this proportion: as the beats in one turn of the great wheel, are to the beats in an hour, so are the hours on the face of the clock (viz 12 or 24), to the quotient of the hour-wheel or dial-wheel divided by the pinion of report, that is, by the number of turns which the pinion of report makes in one turn of the dial-wheel: which in numbers is 26928 : 20196 : : 12 : 9.—Or thus; as the hours of the watch's going, are to the numbers of the turns of the fusee, so are the hours of the face, to the quotient of the pinion of report. So, if the hours be 12, then as 16 : 12 : : 12 : 9; but if 24, then as 16 : 12 : : 24 : 18.

This rule may serve to lay the pinion of report on any other wheel, thus: as the beats in one turn of any wheel, are to the beats in an hour, so are the hours of the face, or dial-plate, of the watch, to the quotient of the dial-wheel divided by the pinion of report, fixed on the spindle of the aforesaid wheel.

PINT, a measure of capacity, being the 8th part of a gallon, both in ale and wine measure, &c. The wine pint contains 29 cubic inches; and the ale pint 35¼ cubic inches. The wine pint of pure spring water, weighs near 17 ounces avoirdupois, and the ale pint a little above 20 ounces.—The Paris pint contains about 2 pounds of common water. And the Scotch pint contains 108¾ cubic inches, and therefore contains 3 English pints.

PISCES, the 12th sign or constellation in the zodiac; in the form of two fishes tied together by the tails. The Greeks, who have some fable to account for the origin of every constellation, tell us, that when Venus and Cupid were one time on the banks of the Euphrates, there appeared before them that terrible giant Typhon, who was so long a terror to all the gods. These deities immediately, they say, threw themselves into the water, and were there changed into these two fishes, the Pisces, by which they escaped the danger. But the Egyptians used the signs of the zodiac as part of their hieroglyphic language, and by the 12 they conveyed an idea of the proper employment during the 12 months of the year. The Ram and the Bull had, at that time, taken to the increase of their flock, the young of those animals being then growing up; the maid Virgo, a reaper in the field, spoke the approach of harvest; Sagittary declared autumn the time for hunting; and the Pisces, or fishes tied together, in token of their being taken, reminded men that the approach of spring was the time for fishing.

The ancients, as they gave one of the 12 months of the year to the patronage of each of the 12 superior deities, so they also dedicated to, or put under the tutelage of each, one of the 12 signs of the zodiac. In this division, the fishes naturally fell to the share of Neptune; and hence arises that rule of the astrologers, which throws every thing that regards the fate of fleets and merchandise, under the more immediate patronage and protection of this constellation.—The stars in the sign Pisces are, in Ptolemy's catalogue 38, in Tycho's 36, in Hevelius's 39, and in the Britannic catalogue 113.

PISCIS *Australis*, the Southern Fish, is a constellation of the southern hemisphere, being one of the old 48 constellations mentioned by the ancients. The Greeks have here again the fable of Venus and her son throwing themselves into the sea, to escape from the terrible Typhon. This fable is probably borrowed from the hieroglyphics of the Egyptians. With them, a fish represented the sea, its element; and Typhon was probably a land flood, perhaps represented by the sign Aquarius, or water-pourer, whose stream or river is represented as swallowed up by this fish, as the land floods and rivers are by the sea. And Venus was some queen, perhaps Semiramis, otherwise called Hamamah, who took to the river or the sea with her son, in a vessel, to avoid the flood, &c. The remarkable star Fomahaut, of the 1st magnitude, is just in the mouth of this fish. The stars of this constellation are, in Ptolemy's catalogue 18, and in Flamsteed's 24.

PISCIS *Volans*, the Flying Fish, is a small constellation of the southern hemisphere, unknown to the ancients, being added by the moderns. It is not visible in our latitude, and contains only 8 stars.

PISTOLE, a gold coin in Spain, Italy, Switzerland, &c, of the value of about 16*s*. 6*d*.

PISTON, a part or member in several machines, particularly pumps, air-pumps, syringes, &c; called also the embolus, and popularly the sucker. The piston of a pump is a short cylinder of wood or metal, fitted exactly to the cavity of the barrel, or body; which, being worked up and down alternately, raises the water; and when raised, presses it again, so as to make it force up a valve with which it is furnished, and so escape through the spout of the pump. There are two sorts of pistons used in pumps; the one with a valve, called a bucket; and the other without a valve, called a forcer.

PITCH, in Music, is the acuteness or graveness of any particular sound, or of the tuning of any instrument. A sound less acute than some other sound with which it is compared, is said to be of a lower pitch than that other sound; and vice versa.

PITISCUS (BARTHOLOMEW), a German mathematician, who died in 1613. He was author of two respectable mathematical works: 1. Trigonometria first, published at Frankfort, in 1599, a large vol. in 4to, being a very complete work on that science, with very large tables of sines, tangents, and secants: it afterwards went through several editions, and was translated into English by Handson, in 1614. See my Tracts, vol. 1, pa. 294.—2. Thesaurus Mathematicus, in folio, 1613, being an edition of the large tables of Rheticus, with all the numerous errors corrected.

PITOT (HENRY), a French mathematician, was born at Aramont in Languedoc, 1695, and died there in 1771, in his 77th year. Pitot learned the mathematics without a master, and repaired to Paris in 1728, where he was admitted a member of the Academy of Sciences in 1724. Besides a vast number of his memoirs printed in the Academy's collection, he published in 1731 the Theory of the Working of Ships, in 1 vol. 4to; a work of considerable merit, which was translated into English, and procured the author's admission into the Royal Society of London. In 1740, the states-general of Languedoc appointed him their chief engineer, with the office of inspector-general of the canal which joins the two seas. That province is indebted to him for several valuable monuments of his genius; and he conducted to Montpellier a copious supply of water, from a distance of 9 miles, a work which is the admiration of all strangers.

PLACE, in Philosophy, that part of infinite space which any body possesses. Aristotle and his followers divide place into External and Internal.

Internal PLACE, is that space or room which the body contains. And

External PLACE, is that which includes or contains the body; which is by Aristotle called the first or concave and immoveable surface of the ambient body.

Newton, better, and more intelligibly, distinguishes place into absolute and relative.

Absolute and *Primary* PLACE, is that part of infinite and immoveable space which a body possesses. And

Relative, or *Secondary* PLACE, is the space it possesses considered with regard to other adjacent objects.

Dr. Clark adds another kind of relative place, which he calls relatively common place; and defines it, that part of any moveable or measurable space which a body possesses; which place moves together with the body.

PLACE, Mr. Locke observes, is sometimes likewise taken for that portion of infinite space possessed by the material world; though this, he adds, were more properly called extension. The proper idea of place, according to him, is the relative position of any thing, with regard to its distance from certain fixed points; whence it is said a thing has or has not changed place, when its distance is or is not altered with respect to those bodies.

PLACE, in Optics, or *Optical* PLACE, is the point to which the eye refers an object.

Optic PLACE of a star, is a point in the surface of the mundane sphere in which a spectator sees the centre of the star, &c.—This is divided into True and Apparent.

True, or *Real Optic* PLACE, is that point of the surface of the sphere, where a spectator at the centre of the earth would see the star, &c.

Apparent, or *Visible Optic* PLACE, is that point of the surface of the sphere, where a spectator at the surface of the earth sees the star, &c.—The distance between these two optic places makes what is called the parallax.

PLACE *of the Sun*, or *Moon*, or *Star*, or *Planet*, in Astronomy, simply denotes the sign and degree of the zodiac which the luminary is in; and is usually expressed either by its latitude and longitude, or by its right ascension and declination.

PLACE *of Radiation*, in Optics, is the interval or space in a medium, or transparent body, through which any visible object radiates.

PLACE, in Geometry, usually called *Locus*, is a line used in the solution of problems, being that in which the determination of every case of the problem lies. See LOCUS, *Plane, Simple, Solid*, &c.

PLACE, in War and Fortification, a general name for all kinds of fortresses, where a party may defend themselves.

PLACE *of Arms*, a strong part where the arms &c, are deposited, and where usually the soldiers assemble and are drawn up.

PLAFOND, or PLATFOND, in Architecture, the ceiling of a room.

PLAIN &c. See PLANE.

PLAN, a representation of something, drawn on a plane. Such as maps, charts, and ichnographies.

PLAN, in Architecture, is particularly used for a draught of a building; such as it appears, or is intended to appear, on the ground; showing the extent, division, and distribution of its area into apartments, rooms, passages, &c. It is also called the ground plot, platform, and ichnography of the building; and is the first device or sketch the architect makes.

Geometrical PLAN, is that in which the solid and vacant parts are represented in their natural proportion.

Raised PLAN, is that where the elevation, or upright, is shown upon the geometrical plan, so as to hide the distribution.

Perspective PLAN, is that which is conducted and exhibited by degradations, or diminutions, according to the rules of perspective.

PLANE, or PLAIN, in Geometry, denotes a plane figure, or a surface lying evenly between its bounding lines: Euclid. Some define a plane, a surface, from every point of whose perimeter a right line may be drawn to every other point in the same, and always coinciding with it.—As the right line is the shortest extent from one point to another, so is a plane the shortest extension between one line and another.

PLANES are much used in astronomy, conic sections, spherics, &c, for imaginary surfaces, supposed to cut and pass through solid bodies. When a plane cuts a cone parallel to one side, it makes a parabola; when it cuts the cone obliquely, an ellipse or hyperbola; and when parallel to its base, a circle. Every section of a sphere is a circle. The sphere is wholly explained by planes, conceived to cut the celestial bodies, and to fill the areas or circumferences of the orbits: and in estimating their inclination, they are all referred to the plane of the earth's orbit, or plane of the ecliptic.

PLANE *of a Dial*, is the surface on which a dial is supposed to be described.

PLANE, in Mechanics. A *Horizontal* PLANE, is a plane that is level, or parallel to the horizon.

Inclined PLANE, is one that makes an oblique angle with a horizontal plane. The doctrine of the motion of bodies on inclined planes, makes a very considerable article in mechanics, and has been fully explained under the articles, MECHANICAL *Powers*, and INCLINED *Plane*.

PLANE *of Gravity*, or *Gravitation*, is a plane supposed to pass through the centre of gravity of the body, and in the direction of its tendency; that is, perpendicular to the horizon.

PLANE *of Reflection*, in Catoptrics, is a plane which passes through the point of reflection; and is perpendicular to the plane of the glass, or reflecting body.

PLANE *of Refraction*, is a plane passing through the incident and refracted ray.

Perspective PLANE, is a plane transparent surface, usually perpendicular to the horizon, and supposed to be placed between the spectator's eye and the object he views; through which the optic rays, emitted from the several points of the object, are supposed to pass to the eye, and in their passage to leave marks that represent them on the said plane.—Some call this the table, or picture, because the draught or perspective of the object is supposed to be upon it. Others call it the section, from its cutting the visual rays; and others again the glass, from its supposed transparency.

Geometrical PLANE, in Perspective, is a plane parallel to the horizon, upon which the object is supposed to be placed that is to be drawn.

Horizontal PLANE, in Perspective, is a plane passing through the spectator's eye, parallel to the horizon.

Vertical PLANE, in Perspective, is a plane passing through the spectator's eye, perpendicular to the geometrical plane, and usually at right angles to the perspective plane.

Objective PLANE, in Perspective, is any plane situate in the horizontal plane, of which the representation in perspective is required.

PLANE *of the Horopter*, in Optics, is a plane passing through the horopter AB, and perpendicular to a plane passing through the two optic axes CH and CI. See the fig. to the article HOROPTER.

PLANE *of the Projection*, is the plane upon which the sphere is projected.

PLANE *Angle*, is an angle contained under two right lines or surfaces.—It is so called in contradistinction to a solid angle, which is formed by three or more planes; and to a spherical angle, contained between two arcs of great circles on a sphere.

PLANE *Triangle*, is a triangle formed by three right lines; in opposition to a spherical and a mixt triangle.

PLANE *Trigonometry* is the doctrine of plane triangles, their measures, proportions, &c.

PLANE *Glass*, or *Mirror*, in Optics, is a glass or mirror having a flat or even surface.

PLANE *Chart*, in Navigation, is a sea-chart, having the meridians and parallels represented by parallel straight lines; and consequently having the degrees of longitude the same in every part. See CHART.

PLANE *Number*, is that which may be produced by the multiplication of two numbers, the one by the other. Thus, 6 is a plane number, being produced by the multiplication of the two numbers 2 and 3; also 15 is a plane number, being produced by the multiplication of the numbers 3 and 5. See NUMBER.

PLANE *Place*, *Locus Planus*, or *Locus ad Planum*, is a term used by the ancient geometricians, for a geometrical locus, when it was a right line or a circle, in opposition to a solid place, which was one of the conic sections. These plane loci are distinguished by the moderns into loci ad rectum, and loci ad circulum. See LOCUS.

PLANE *Problem*, is such a one as cannot be resolved geometrically, but by the intersection either of a right line and a circle, or of the circumferences of two circles. Such as the following: viz, Given the hypothenuse, and the sum of the other two sides, of a right-angled triangle; to find the triangle. Or this: Of four given lines to form a trapezium of a given area.

PLANE *Sailing*, in Navigation, is the art of working the several cases and varieties in a ship's motion on a plane chart; or of navigating a ship upon principles deduced from the notion of the earth's being an extended plane. This principle, though notoriously false, yet places being laid down accordingly, and a long voyage broken into many short ones, the voyage may be performed tolerably well by it, especially near the same meridian.

In plain sailing, it is supposed that these three, the rhumb line, the meridian, and parallel of latitude, will always form a right-angled triangle; and so posited, as that the perpendicular side will represent part of the meridian, or north and south line, containing the difference of latitude; the base of the triangle, the departure, or east and west line; and the hypothenuse the distance sailed. The angle at the vertex is the course; and the angle at the base, the complement of the course; any two of which, besides the right angle, being given, the triangle may be protracted, and the other three parts found.—For the doctrine of plane sailing, see SAILING.

PLANE *Scale*, is a thin ruler, on which are graduated the lines of chords, sines, tangents, secants, leagues, rhumbs, &c; being of great use in most parts of the mathematics, but especially in navigation. See its description and use under SCALE.

PLANE *Table*, an instrument much used in land-surveying; by which the draught or plan is taken upon the spot, as the survey or measurement goes on, without any future protraction, or plotting. This instrument consists of a plane rectangular board, of any convenient size, the centre of which, when used, is fixed by means of screws to a three-legged stand, having a ball and socket, or universal joint, at the top, by means of which, when the legs are fixed on the ground, the table is inclined in any direction. To the table belongs,

1. A frame of wood, made to fit round its edges, for the purpose of fixing a sheet of paper upon the table. The one side of this frame is usually divided into equal parts, by which to draw lines across the table, parallel or perpendicular to the sides; and the other side of the frame is divided into 360 degrees, from a centre which is in the middle of the table; by means of which the table is to be used as a theodolite, &c.

2. A magnetic needle and compass screwed into the side of the table, to point out directions and be a check upon the sights.

3. An index, which is a brass two-foot scale, either with a small telescope, or open sights erected perpendicularly upon the ends. These sights and the fiducial edge of the index are parallel, or in the same plane.

General Use of the PLANE *Table*.

To use this instrument properly, take a sheet of writing or drawing paper, and wet it to make it expand; then spread it flat upon the table, pressing down the frame upon the edges, to stretch it, and keep it fixed there; and when the paper is become dry, it will, by shrinking again, stretch itself smooth and flat from any cramps or unevenness. Upon this paper is to be drawn the plan or form of the thing measured.

The general use of this instrument, in land-surveying, is to begin by setting up the table at any part of the ground you think the most proper, and make a point upon a convenient part of the paper or table, to represent that point of the ground; then fix in that point of the paper one leg of the compasses, or a fine steel pin, and apply to it the fiducial edge of the index, moving it round the table, close by the pin, till through the sights you perceive some point or remarkable object, as the corner of a field, or a picket set up, &c; and from the station point draw a dry or obscure line along the fiducial edge of the index. Then turn the index to another object, and draw a line on the paper towards it. Do the same by another; and so on till as many objects are set as may be thought necessary. Then measure from your station towards as many of the objects as may be necessary, and no more, taking the requisite offsets to corners or crooks in the hedges, &c; laying the measured distances, from a proper scale, down upon the respective lines on the paper. Then move the table to any of the proper places measured to, for a second station, fixing it there in the original position, turning it about its centre for that purpose, both till the magnetic needle point to the same degree of the compass as at first, and also by laying the fiducial edge of the index along the line between the two stations, and turning the table till through the index the former station can be seen; and then fix the table there: from this new station repeat the same operations as at the former; setting several objects, that is, drawing lines towards them, on the paper, by the edge of the index, measuring and laying off the distances. And thus proceed from station to station; measuring only such lines as are necessary, and determining as many as you can by intersecting lines of direction drawn from different stations.

Of Shifting the Paper on the PLANE *Table.* When one paper is full of the lines &c measured, and the survey is not yet completed; draw a line in any manner through the farthest point of the last station line to which the work can be conveniently laid down; then take the sheet off the table, and fix another fair sheet in its place, drawing a line upon it, in a part of it the most convenient for the rest of the work, to represent the line drawn at the end of the work on the former paper. Then fold or cut the old sheet by the line drawn upon it; apply it so to the line on the new sheet, and, as they lie together in that position, continue or produce the last station line of the old sheet upon the new one; and place upon it the remainder of the measurement of that line, beginning at where the work left off on the old sheet. And so on, from one sheet to another, till the whole work is completed.

But it is to be noted, that if the said joining lines, upon the old and new sheet, have not the same inclination to the side of the table, the needle will not respect or point to the original degree of the compass, when the table is rectified. But if the needle be required to respect still the same degree of the compass, the easiest way then of drawing the lines in the same position, is to draw them both parallel to the same sides of the table, by means of the equal parallel divisions marked on the other two sides of the frame.

When the work of surveying is done, and you would fasten all the sheets together into one piece, or rough plan, the aforesaid lines are to be accurately joined together, in the same manner as when the lines were transferred from the old sheets to the new ones.

PLANET, or *Wandering Star*, in Astronomy, is a celestial body revolving about the sun, or some other planet, as a centre, or focus, in nearly a circular orbit, or in an ellipse of small excentricity.

The planets are usually distinguished into primary and secondary.

Primary PLANETS, are those that revolve about the sun as a centre, or focus; such as Mercury, Venus, the earth, &c.

Secondary PLANETS, are such as revolve about a primary planet as a centre, as the primary ones do about the sun; being more commonly called satellites; such is our moon, and the satellites of Jupiter, Saturn, and Uranus. See SATELLITE.

The primary planets are again distinguished into Superior and Inferior.

The *Superior* Planets are those which are above the earth, or farther from the sun; as Mars, Vesta, Juno, &c.

The *Inferior* Planets are those that are below the earth, as Mercury and Venus.

Till very lately the number of the primary planets was esteemed only six, which it was thought constituted the whole of our planetary system: these were Mercury, Venus, Earth, Mars, Jupiter, and Saturn; all of which it appears have been known from the highest antiquity.

But the great perfection to which telescopes have been brought, has, within a few years, nearly doubled the number of the planets. Dr. Herschel discovered Uranus at Bath, March 13, 1781. This planet was first named, in honour of his present majesty, the Georgium Sidus, while some astronomers called it Herschel, from its discoverer; but both these names have now given way to that of Uranus.

An eighth planet, Ceres, was discovered by Piazzi, at Palermo in Italy, January 1st, 1801.

A ninth, Pallas, was discovered by Dr. Olbers, at Bremen, on March 28th, 1802.

A tenth, Juno, was first observed by Mr. Harding, at Lilienthal near Bremen, on the 1st of September 1804.

And finally, another new planet, Vesta, making the number of planets in our system eleven, was discovered by Dr. Olbers, at Bremen, March 29th, 1807; being the second that this celebrated astronomer had discovered in 5 years. Four out of the five new planets have their orbits between those of Mars and Jupiter; these are Vesta, Juno, Pallas, and Ceres; but the other, Uranus, is the highest in our system. The order of the planets is therefore as follows; Mercury, Venus, Earth, Mars, Vesta, Juno, Pallas, Ceres, Jupiter, Saturn, and Uranus.

The planets were represented by the same characters as the chemists use to represent their metals by, on account of some supposed analogy between those celestial and the subterraneous bodies. Thus,

Mercury, the messenger of the Gods, represented by ☿, the same as that metal, imitating a man with wings on his head and feet, is a small bright planet, with a light tinct of blue, the sun's constant attendant, from whose side it never departs above 28 degrees, and by that means is usually hid in his splendour. It performs its course around him in about 3 months.

Venus, the goddess of love, marked ♀, from the figure of a woman, the same as denotes copper, from a slight tinge of that colour, or verging to a light straw colour. She is a very bright planet, revolving next above Mercury, and never appears above 48 degrees from the sun, finishing her course about him in about 7 months. When this planet goes before the sun, or is a morning star, it has been called Phosphorus, and also Lucifer; and when following him, or when it shines in the evening as an evening star, it is called Hesperus.

Tellus, the Earth, next above Venus, is denoted by ⊖, and performs its course about the sun in the space of a year.

Mars, the god of war, characterized ♂, a man holding out a spear, the same as iron, is a ruddy fiery-coloured planet, and finishes his course about the sun in about 2 years.

Vesta, Juno, Pallas, Ceres, are the planets next in order, and their periods of revolution about the sun are as below: Vesta in days; Juno in 2007½ days; Pallas in 1682 days; and Ceres in 1681 days. These four planets are too small to be distinguished by the naked eye.

Jupiter, the chief god, or thunderer, marked ♃, to represent the thunderbolts, denoting the same as tin, from his pure white brightness. This planet is next above Mars, and completes its course round the sun in about 12 years.

Saturn, the father of the Gods, is expressed by ♄, to imitate an old man supporting himself with a staff, and is the same as denotes lead, from his feeble light and dusky colour. He revolves next above Jupiter, and performs his course in about 30 years.

Lastly, Uranus, the Georgian, or Herschel, is denoted by ♅, the initial of his name, with a cross for the Christian planet, or that discovered by the Christians. This is the highest, or outermost, of the known planets, and revolves around the sun in the space of about 90 years.

It is to be regretted that all the new planets have not been called by the names of their respective discoverers, instead of the fanciful and unmeaning names that have been imposed on them by the continental astronomers.

From these descriptions a person may easily distinguish all the old planets. For if, after sun-set, he sees a planet nearer the east than the west, he may conclude it is neither Venus nor Mercury; and he may determine whether it is Saturn, Jupiter, or Mars, by the colour, light, and magnitude: by which also he may distinguish between Venus and Mercury.

It is probable that all the planets are dark opake bodies, similar to the earth, and for the following reasons.

1. Because, in Mercury, Venus, and Mars, only that part of the disk is found to shine which is illuminated by the sun; and again, Venus and Mercury, when between the sun and the earth, appear like maculæ or dark spots on the sun's face: from which it is evident, that those three planets are opake bodies, illuminated by the borrowed light of the sun. And the same appears of Jupiter, from his being void of light in that part to which the shadow of his satellites reaches, as well as in that part turned from the sun: and that his satellites are opake, and reflect the sun's light, like the moon, is abundantly shown. Moreover, since Saturn, with his ring and satellites, and also Herschel, with his satellites, only yield a pale light, considerably fainter than that of the rest of the planets, and than that of the fixed stars, though these be vastly more remote; it is past a doubt that these planets too, with their attendants, are opake bodies.

2. Since the sun's light is not transmitted through Mercury or Venus, when placed against him, it is plain they are dense opake bodies; which is likewise evident of Jupiter, from his hiding the satellites in his shadow; and therefore, by analogy, the same may be concluded of Saturn, and all the rest.

3. From the variable spots of Venus, Mars, and Jupiter, it is evident that these planets have a changeable atmosphere; which kind of atmosphere, by a like argument, may be inferred of the satellites of Jupiter; and therefore, by similitude, the same may be concluded of the other planets.

4. In like manner, from the mountains observed in the moon and Venus, the same may be supposed in the other planets.

5. Lastly, since all these planets are opake bodies, shining with the sun's borrowed light, are furnished with mountains, and are encompassed with a changeable atmosphere; we may infer that they have waters, seas &c, as well as dry land, and are bodies like the moon, and therefore like the earth. And hence, it seems also probable, that the other planets have their animal inhabitants, as well as our earth has.

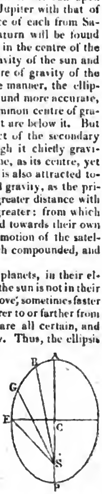
Of the Orbits of the PLANETS.

Though all the primary planets revolve about the sun, their orbits are not circles, but ellipses, having the sun in one of the foci. This circumstance was first discovered by Kepler, from the observations of Tycho Brahé: before that, all astronomers took the planetary orbits for excentric circles. All the planes of these orbits intersect in the sun; and the line in which the plane of each orbit cuts that of the earth, is called the Line of the nodes; and the two points in which the orbits themselves touch that plane, are the Nodes; also the angle in which each plane cuts that of the ecliptic, is called the Inclination of the plane or orbit.—The distance between the centre of the sun, and the centre of each orbit, is called the excentricity of the planet, or of its orbit.

The Motions of the PLANETS.

The motions of the primary planets are very simple, and tolerably uniform, as being compounded only of a projectile motion, forward in a right line, which is a tangent to the orbit, and a gravitation towards the sun at the centre. Besides, being at such vast distances from each other, the effects of their mutual gravitation towards one another are in a considerable degree, though not altogether, insensible: for the action of Jupiter upon Saturn, for ex. is found to be $\frac{1}{211}$ of the action of the sun upon Saturn, by comparing the matter of Jupiter with that of the sun, and the square of the distance of each from Saturn. So that the elliptic orbit of Saturn will be found more just, if its focus be supposed not in the centre of the sun, but in the common centre of gravity of the sun and Jupiter, or rather in the common centre of gravity of the sun and all the other planets. In like manner, the elliptic orbit of any other planet will be found more accurate, by supposing its focus to be in the common centre of gravity of the sun and all the planets that are below it. But the matter is far otherwise, in respect of the secondary planets: for every one of these, though it chiefly gravitates towards its respective primary one, as its centre, yet at equal distances from the sun, it is also attracted towards him with an equally accelerated gravity, as the primary one is towards him; but at a greater distance with less, and at a nearer distance with greater: from which double tendency towards the sun, and towards their own primary planets, it happens, that the motion of the satellites, or secondary planets, is very much compounded, and affected with various inequalities.

The motions even of the primary planets, in their elliptic orbits, are not equable, because the sun is not in their centre, but their focus. Hence they move sometimes faster and sometimes slower, as they are nearer to or farther from the sun; but yet these irregularities are all certain, and follow according to an immutable law. Thus, the ellipsis PEA &c, representing the orbit of a planet, and the focus S the sun's place: the axis of the ellipse AP, is the line of the apses; the point A, the higher apsis or aphelion; P the lower apsis or perihelion; CS the excentricity; and ES the planet's mean distance from the sun. Now the motion of the planet in its perihelion P is swiftest, but in its aphelion A it is slowest; and at E the motion as well as the distance is a mean, being there such as would describe the whole orbit in the same time it is really described in. And the law by which the motion in every point is regulated, is this, that a line or radius drawn from the centre of the sun to the centre of the planet, and thus carried along with an angular motion, always describes an elliptic area proportional to the time; that is, the trilineal area ASB, is to the area ASG, as the time the planet is in moving over AB, to the time it is in moving over AG. This law was first discovered by Kepler, from observations; and



has since been accounted for and demonstrated by Sir Isaac Newton, from the general laws of attraction and projectile motion.

As to the periods and velocities of the planets, or the times in which they perform their courses, they are found to have a wonderful harmony with their distances from the sun, and with one another: the nearer each planet being to the sun, the quicker still is its motion, and its period the shorter, according to this general and regular law; viz, that the squares of their periodical times are as the cubes of their mean distances from the sun or focus of their orbits. The knowledge of this law we owe also to the sagacity of Kepler, who found that it obtained in all the primary planets; as astronomers have since found it also to hold good in the secondary ones. Kepler indeed deduced this law merely from observation, by a comparison of the several distances of the planets with their periods or times: the glory of investigating it from physical principles is due to Sir Isaac Newton, who has demonstrated that, in the present state of nature, such a law was inevitable.

The phenomena of the planets are, their Conjunctions, Oppositions, Elongations, Stations, Retrogradations, Phases, and Eclipses; for which see the respective articles. For a view of the comparative magnitudes of the planets, and of their several distances, &c; see the articles Orbit and Solar System, as also Plate 26, fig. 1.—The following Table contains a synopsis of the distances, magnitudes, periods, &c, of the several planets, according to the latest observations and improvements.

TABLE *of the* PLANETARY MOTIONS, DISTANCES, &c.

Anno 1815	Mercury	Venus.	Earth.	Mars.	Vesta, or Olbers'.	Juno, or Harding.	Pallas, or Olbers'.	Ceres, or Piazzi.	Jupiter.	Saturn.	Uranus, or Herschel, 1782.
Greatest elongation of inferior, and parallax of superior planets.	28° 20′	47° 48′	※ ※	47° 24′					11° 51′	6° 29′	3° 4′½
Periodical revolutions round the sun.	d h m 87 23 1[illegible]	d h m 224 16 49	d h m 365 6 9½	d h m 686 23 31		2007½ ds	1682 ds.	1681 ds.	d h m 4332 14 2[illegible]	d h m 10759 1 51	d h 30689 0
Diurnal rotations upon their axes	※ ※ ※	23h 20m	23h 56m 4s	24h 40m 22s					9h 56m	10h 17m	※ ※
Inclinations of their orbits to the ecliptic.	7° 0′	3° 23′½	※ ※	1° 51′	7° 8′⅓	13° 4′	34° 38′	10° 38′	1° 19′	2° 30′	0° 46′½
Place of the ascending node.	1s 15° 47′	2s 14° 44′	※ ※ ※	1s 17° 39′	1s 13° 18′	5s 21° 4′	5s 22° 31′	2s 21° 7′	3s 8° 50′	4s 21° 48′	3s 13° 1′
Place of the aphelion, or point farthest from the sun.	8s 14° 13′	10s 9° 36′	9s 9° 15′½	5s 2° 6′½		7s 22° 49′	10s 4′ 36″	10s 26° 9′	6s 10° 37′½	9s 0° 45′½	11s 23° 23′
Greatest apparent diameters, seen from the earth.	11″	58″	※	27″			0·5″	1″	39″	18″	4″
Diameter in English miles; that of the sun being 883217.	3224	7867	7914	4189			80	163	89170	79042	35109
Proportional mean distances from the sun.	38710	72333	100000	152369	235513	266400	276700	276300	520259	954072	1918362
Mean distances from the sun in semidiameters of the earth.	9210	17210	23799	36262	56049	63400	65804	65851	123778	227028	452000

Proportion of density; that of the sun being ¼.	2	1¼	1	·7					·23	·09	※

A planet's motion, or distance from its apogee, is called the mean anomaly of the planet, and is measured by the area it describes in the given time: when the planet arrives at the middle of its orbit, or the point E, the area or time is called the true anomaly. When the planet's motion is reckoned from the first point of Aries, it is called its motion in longitude; which is either mean or true; viz, mean, which is such as it would have were it to move uniformly in a circle; and true, which is that with which the planet actually describes its orbit, and is measured by the arc of the ecliptic it describes. And hence may be found the planet's place in its orbit for any given time after it has left the aphelion: for suppose the area of the ellipsis be so divided by the line SG, that the whole elliptic area may have the same proportion to the part ASG, as the whole periodical time in which the planet describes its whole orbit, has to the given time; then will G be the planet's place in its orbit sought.

PLANETARIUM, an astronomical machine, contrived to represent the motions, orbits, &c, of the planets, as they really are in nature, or according to the Copernican system. The larger kind of them are called Orreries. See ORRERY.

A remarkable machine of this sort was invented by Huygens, and described in his Opusc. Posth. tom. 2. p. 157, edit. Amst. 1728, which is still preserved among the curiosities of the university at Leyden. In this planetarium, the five primary planets perform their revolutions about the sun, and the moon performs her revolution about the earth, in the same time that they are really performed in the heavens. Also the orbits of the moon and planets are represented with their true proportions, excentricity, position, and declination from the ecliptic or orbit of the earth. So that by this machine the situation of the planets, with the conjunctions, oppositions, &c, may be known, not only for the present time, but for any other time, either past or yet to come; as in a perpetual ephemeris.

There was exhibited in London, viz, in the year 1791, a still much more complete planetarium of this kind; called "a planetarium or astronomical machine, which exhibited the most remarkable phenomena, motions, and revolutions of the universe. Invented, and partly executed, by the celebrated M. Phil. Matthew Hahn, member of the academy of sciences at Erfurt. But finished and completed by Mr. Albert de Mylius." This is a most stupendous and elaborate machine; consisting of the solar system in general, with all the orbits and planets in their due proportions and positions; as also the several particular planetary systems of such as have satellites, as of the earth, Jupiter, &c; the whole kept in continual motion by a chronometer, or grand eight-day clock; by which all these systems are made perpetually to perform all their motions exactly as in nature, exhibiting at all times the true and real motions, positions, aspects, phenomena, &c, of all the celestial bodies, even to the very diurnal rotation of the planets, and the unequal motions in their elliptic orbits. A description was published of this most superb machine; and it was purchased and sent as one of the presents to the emperor of China, in the embassy of Lord Macartney, in the year 1793.

But the planetariums or orreries now most commonly used, do not represent the true times of the celestial motions, but only their proportions; and are not kept in continual motion by a clock, but are only turned round occasionally with the hand, in order to give young beginners an idea of the planetary system; as also, if constructed with sufficient accuracy, to resolve problems, in a coarse way, relating to the motions of the planets, and of the earth and moon, &c.

Dr. Desaguliers (Exp. Philos. vol. 1, p. 430,) describes a planetarium of his own contrivance, which is one of the best of the common sort. The machine is contrived to be rectified or set to any latitude; and then by turning the handle of the planetarium, all the planets perform their revolutions round the sun in proportion to their periodical times, and they carry indices which show the longitudes of the planets, by pointing to the divisions graduated on circles for that purpose.

The planetarium represented in fig. 1, plate 22, is an instrument contrived by Mr. Wm. Jones, of Holborn, London, mathematical instrument maker, who has paid considerable attention to such machines, to bring them to a great degree of simplicity and perfection. It represents in a general manner, by various parts of its machinery, all the motions and phenomena of the planetary system. This machine consists of, the Sun in the centre, with the Planets in the order of their distance from him, viz, Mercury, Venus, the Earth and Moon, Mars, Jupiter with his moons, and Saturn with his ring and moons; and to it is also occasionally applied an extra long arm for the Georgian Planet and his moons. To the earth and moon is applied a frame CD, containing only four wheels and two pinions, which serve to preserve the earth's axis in its due parallelism in its motion round the sun, and to give the moon at the same time her due revolution about the earth. These wheels are connected with the wheel-work in the round box below, and the whole is set in motion by the winch H. The arm M that carries round the moon, points out on the plate C her age and phases for any situation in her orbit, upon which they are engraved. In like manner the arm points out her place in the ecliptic B, in signs and degrees, called her geocentric place, that is, as seen from the earth. The moon's orbit is represented by the flat rim A; the two joints of it, upon which it turns, denoting her nodes; and the orbit being made to incline to any required angle. The terrella, or little earth, of this machine, is usually made of a three-inch globe papered, &c, for the purpose; and by means of the terminating wire that goes over it, points out the changes of the seasons, and the different lengths of days and nights more conspicuously. By this machine are seen at once all the planets in motion about the Sun, with the same respective velocities and periods of revolution which they have in the heavens; the wheelwork being calculated to a minute of time, from the latest discoveries. See Mr. Jones's Description of his new portable Orrery.

PLANETARY, something that relates to the planets. Thus we say, planetary worlds, planetary inhabitants, planetary motions, &c. Huygens and Fontenelle bring several probable arguments for the reality of planetary worlds, animals, plants, men, &c.

PLANETARY *System*, is the system or assemblage of the planets, primary and secondary, moving in their respective orbits, round their common centre the sun. See *Solar* SYSTEM.

PLANETARY *Days*. With the ancients, the week was shared among the seven planets, each planet having its day. This we learn from Dion Cassius and Plutarch, Sympos. lib. 4. q. 7. Herodotus adds, that it was the Egyptians who first discovered what god, that is what planet, presides over each day; for that among this people the planets were directors. And hence it is, that in most European languages the days of the week are still denominated from the planets; as sunday, monday, &c.

PLANETARY *Dials*, are such as have the planetary hours inscribed on them.

PLANETARY *Hours*, are the 12th parts of the artificial day and night. See *Planetary* HOUR.

PLANETARY *Squares*, are the squares of the seven numbers from 3 to 9, disposed magically. Cornelius Agrippa, in his book of magic, has given the construction of the seven planetary squares. And M. Poignard, canon of Brussels, in his treatise on sublime squares, gives new, general, and easy methods, for making the seven planetary squares, and all others to infinity, by numbers in all kinds of progressions. See MAGIC *Square*.

PLANETARY *Years*, the periods of time in which the several planets make their revolutions round the sun, or earth.—As from the proper revolution of the earth, or the apparent revolution of the sun, the solar year takes its original; so from the proper revolutions of the rest of the planets about the earth, as many kinds of years arise; viz, the Saturnian year, which is defined by 29 Egyptian years 174 days 58 minutes, equivalent in a round number to 30 solar years. The Jovial year, containing 11 years 317 days 14 hours 27 minutes. The Martial year, containing 1 year 321 days 23 hours 31 minutes. For Venus and Mercury, as their years, when judged of with regard to the earth, are almost equal to the solar year; they are more usually estimated from the sun, the true centre of their motions: in which case the former is equal to 224 days 16 hours 49 minutes; and the latter to 87 days 23 hours 16 minutes.

PLANIMETRY, that part of geometry which considers lines and plane figures, without any regard to heights or depths.—Planimetry is particularly restricted to the mensuration of planes and other surfaces; as contradistinguished from stereometry, or the mensuration of solids, or capacities of length, breadth, and depth.—Planimetry is performed by means of the squares of long measures, as square inches, square feet, square yards, &c; that is, by squares whose side is an inch, a foot, a yard, &c. So that the area or content of any surface is said to be found, when it is known how many such square inches, feet, yards, &c, it contains. See MENSURATION and SURVEYING.

PLANISPHERE, a projection of the sphere, and its various circles, on a plane; as upon paper or the like. In this sense, maps of the heavens and the earth, exhibiting the meridians and other circles of the sphere, may be called planispheres.

Planisphere is sometimes also considered as an astronomical instrument, used in observing the motions of the heavenly bodies; being a projection of the celestial sphere upon a plane, representing the stars, constellations, &c, in their proper situations, distances, &c. As the Astrolabe, which is a common name for all such projections.

In all planispheres, the eye is supposed to be in a point, viewing all the circles of the sphere, and referring them to a plane beyond them, against which the sphere is as it were flattened: and this plane is called the Plane of Projection, which is always some one of the circles of the sphere itself, or parallel to some one.

Among the infinite number of planispheres which may be furnished by the different planes of projection, and the different positions of the eye, there are two or three that have been preferred to the rest. Such as that of Ptolemy, where the plane of projection is parallel to the equator: that of Gemma Frisius, where the plane of projection is the colure, or solstitial meridian, and the eye the pole of the meridian, being a stereographical projection: or that of John de Royas, a Spaniard, whose plane of projection is a meridian, and the eye placed in the axis of that meridian, at an infinite distance; being an orthographical projection, and called the Analemma.

PLANO-*Concave* glass or lens, is that which is plane on one side, and concave on the other. And

PLANO-*Convex* glass or lens, is that which is plane on one side, and convex on the other. See LENS.

PLAT-BAND, in Architecture, is any flat square moulding, whose height much exceeds its projecture. Such are the faces of an architrave, and the plat-bands of the modillions of a cornice.

PLATFORM, in Artillery and Gunnery, a small elevation, or a floor of wood, stone, or the like, on which cannon, &c, are placed, for more conveniently working and firing them.

PLATFORM, in Architecture, a row of beams that support the timber-work of a roof, lying on the top of the walls, where the entablature ought to be raised. Also a kind of flat walk, or plane floor, on the top of a building; whence a fair view may be taken of the adjacent grounds. So, an edifice is said to be covered with a platform, when it has no arched roof.

PLATO, one of the most celebrated among the ancient philosophers, being the founder of the sect of the Academics, was the son of Aristo, and born at Athens, about 429 years before Christ. He was of a royal and illustrious family, being descended by his father from Codrus, and by his mother from Solon. The name given him by his parents was Aristocles; but being of a robust make, and remarkably broad-shouldered, from this circumstance he was nick-named Plato by his wrestling-master, which name he retained ever after.

From his infancy, Plato distinguished himself by his lively and brilliant imagination. He eagerly imbibed the principles of poetry, music, and painting. The charms of philosophy however prevailing, drew him from those of the fine arts; and at the age of twenty he attached himself to Socrates only, who called him the Swan of the Academy. The disciple profited so well of his master's lessons, that at twenty-five years of age he had the reputation of a consummate sage. He lived with Socrates for eight years, in which time he committed to writing, according to the custom of the students, the purport of a great number of his master's excellent lectures, which he digested by way of philosophical conversations; but made so many judicious additions and improvements of his own, that Socrates, hearing him one day recite his Lysis, cried out, O Hercules! how many fine sentiments does this young man ascribe to me, that I never thought of! And Laertius assures us, that he composed several discourses which Socrates had no manner of hand in. At the time when Socrates was first arraigned, Plato was a junior senator, and he assumed the orator's chair to plead his master's cause, but was interrupted in that design, and the judges passed sentence of condemnation upon Socrates. Upon this occasion Plato begged him to accept from him a sum of money sufficient to purchase his enlargement, but Socrates peremptorily refused the generous offer, and suffered himself to be put to death.

The philosophers who were at Athens were so alarmed at the death of Socrates, that most of them fled, to avoid the cruelty and injustice of the government. Plato retired, till the storm should be over, to Megara, where he was kindly entertained by Euclid the philosopher, who had been one of the first scholars of Socrates. Afterwards he determined to travel in pursuit of knowledge; and from Megara he went to Italy, where he conferred with Eurytus, Philolaus, and Archytas, the most celebrated of the Pythagoreans, from whom he learned all his natural philosophy, diving into the most profound and mysterious secrets of the Pythagoric doctrines. But perceiving other knowledge to be connected with them, he went to Cyrene, where he studied geometry and other branches of mathematics under Theodorus, a celebrated master.

Hence he travelled into Egypt, to learn the theology of their priests, with the sciences of arithmetic, astronomy, and the nicer parts of geometry. Having taken also a survey of the country, with the course of the Nile and the canals, he settled some time in the province of Sais, learning of the sages there their opinions concerning the universe, whether it had a beginning, whether it moved wholly or in part, &c; also concerning the immortality and transmigration of souls: and here it is also thought he had some communication with the books of Moses.

Plato's curiosity was not yet satisfied. He travelled into Persia, to consult the magi as to the religion of that country. He designed also to have penetrated into India, to learn of the Brachmans their manners and customs; but was prevented by the wars in Asia.

Afterwards, returning to Athens, he applied himself to the teaching of philosophy, opening his school in the Academia, a place of exercise in the suburbs of the city; whence it was that his followers took the name of Academics.

Yet, settled as he was, he made several excursions abroad: one in particular to Sicily, to view the fiery ebullitions of Mount Etna. Dionysius the tyrant then reigned at Syracuse, where Plato went to visit him; but, instead of flattering him like a courtier, he reproved him for the disorders of his court, and the injustice of his government. The tyrant, not used to disagreeable truths, was enraged at Plato, and would have put him to death, if Dion and Aristomenes, formerly his scholars, and then favourites of that prince, had not powerfully interceded for him. Dionysius however delivered him into the hands of an envoy of the Lacedemonians, who were then at war with the Athenians: and this envoy, touching on the coast of Ægina, sold him for a slave to a merchant of Cyrene; who, as soon as he had bought him, liberated him, and sent him home to Athens.

Some time after, he made a second voyage into Sicily, in the reign of Dionysius the younger; who sent Dion, his minister and favourite, to invite him to court, that he might learn from him the art of governing his people well. Plato accepted the invitation, and went; but the intimacy between Dion and Plato raising jealousy in the tyrant, the former was disgraced, and the latter sent back to Athens. But Dion, being taken into favour again, persuaded Dionysius to recall Plato, which he did, and received him with all the marks of goodwill and friendship that a great prince could bestow. He sent out a fine galley to meet him, and went himself in a magnificent chariot, attended by all his court, to receive him. But this prince's uneven temper hurried him into new suspicions. It seems indeed that these apprehensions were not altogether groundless: for Ælian says, and Cicero was of the same opinion, that Plato taught Dion how to dispatch the tyrant, and to deliver the people from oppression. However this may be, Plato was offended and complained; and Dionysius, incensed at these complaints, resolved to put him to death: but Archytas, who had great interest with the tyrant, being informed of it by Dion, interceded for the philosopher, and obtained leave for him to retire.

The Athenians received him joyfully at his return, and offered him the administration of the government; but he declined that honour, choosing rather to live quietly in the Academy, in the peaceable contemplation and study of philosophy; being indeed so desirous of a private retirement that he never married. His fame drew disciples from all parts, when he would admit them, as well as invitations to come to reside in many of the other Grecian states; but the three of his pupils that most distinguished themselves, were Speusippus his nephew, who continued the Academy after him, Xenocrates the Caledonian, and the celebrated Aristotle. It is said also that Theophrastus and Demosthenes were two of his disciples. He had it seems so great a respect for the science of geometry and the mathematics, that he had the following inscription painted in large letters over the door of his academy; LET NO ONE ENTER HERE, UNLESS HE HAS A TASTE FOR GEOMETRY AND THE MATHEMATICS!

But as his great reputation gained him on the one hand many disciples and admirers, so on the other it raised him some emulators, especially among his fellow-disciples, the followers of Socrates. Xenophon and he were particularly disaffected to each other. Plato was of so quiet and even a temper of mind, even in his youth, that he never was known to express a pleasure with any greater emotion than that of a smile; and he had such a perfect command of his passions, that nothing could provoke his anger or resentment; from hence, and the subject and style of his writings, he acquired the appellation of the Divine Plato. But though he was naturally of a reserved and very pensive disposition; yet, according to Aristotle, he was affable, courteous, and perfectly good-natured; and sometimes would condescend to crack little innocent jokes on his intimate acquaintances. Of his affability there needs no greater proof than his civil manner of conversing with the philosophers of his own times, when pride and envy were at their height. His behaviour to Diogenes is always mentioned in his history. This Cynic was greatly offended, it seems, at the politeness and fine taste of Plato, and used to catch all opportunities of snarling at him. Dining one day at his table with other company, when trampling upon the tapestry with his dirty feet, he uttered this brutish sarcasm, "I trample upon the pride of Plato:" to which the latter wisely and calmly replied, "with a greater pride."

This extraordinary man, being arrived at 81 years of age, died on his birth-day a very easy and peaceable death, in the midst of an entertainment, according to some; but, according to Cicero, as he was writing. Both the life and death of this philosopher were calm and undisturbed; and indeed he was finely composed for happiness. Besides the advantages of a noble birth, he had a large and comprehensive understanding, a vast fund of wit and good taste, great evenness and sweetness of temper, cultivated and refined by education and travel; so that it is no wonder he was honoured by his countrymen, esteemed by strangers, and adored by his scholars. Tully perfectly adored him: he tells us that he was justly called by Panætius, the divine, the most wise, the most sacred, the Homer of philosophers; thinks, that if Jupiter had spoken Greek, he would have done it in Plato's style, &c. But, panegyric aside, Plato was certainly a very wonderful man, of a large and comprehensive mind, an imagination infinitely fertile, and of a most flowing and copious eloquence. However, the strength and heat of fancy prevailing over judgment in his composition, he was too apt to soar beyond the limits of earthly things, to range in the imaginary regions of general and abstracted ideas; on which account, though there is always a greatness and sublimity in his manner, he did not philosophize so much according to truth and nature as Aristotle, though Cicero did not scruple to give him the preference.

The writings of Plato are all in the way of dialogue, where he seems to deliver nothing from himself, but every thing as the sentiments and opinions of others, of Socrates chiefly, of Timæus, &c. His style, as Aristotle observed, is between prose and verse: on which account some have not scrupled to rank him among the poets: and indeed, besides the elevation and grandeur of his style, his matter is frequently the offspring of imagination, instead of doctrines or truths deduced from nature. The first edition of Plato's works in Greek, was printed by Aldus at Venice in 1513: but a Latin version of them by Marsilius Ficinus had been printed there in 1491. They were reprinted together at Lyons in 1588, and at Francfort in 1602. The famous printer Henry Stephens, in 1578, gave a beautiful and correct edition of Plato's works at Paris, with a new Latin version by Serranus, in three volumes folio.—And the industrious Thomas Taylor has lately given us several of Plato's works in an English translation.

PLATONIC, something that relates to Plato, his school, philosophy, opinions, or the like.

PLATONIC *Bodies*, so called from Plato who treated of them, are what are otherwise called the regular bodies. They are five in number; the tetraedron, the hexaedron, the octaedron, the dodecaedron, and the icosaedron. See each of these articles, as also REGULAR BODIES.

PLATONIC *Year*, or the *Great Year*, is a period of time determined by the revolution of the equinoxes, or the time in which the stars and constellations return to their former places, in respect of the equinoxes.—The Platonic year, according to Tycho Brahé, is 25816 solar years, according to Riccioli 25920, and according to Cassini 24800 years. —This period being once accomplished, it was an opinion among the ancients, that the world was to begin anew, and the same series of things to return over again.

PLATONISM, the doctrine and sentiments of Plato and his followers, with regard to philosophy, &c. His disciples were called Academics, from Academia, the name of a villa in the suburbs of Athens where he opened his school. Among these were Xenocrates, Aristotle, Lycurgus, Demosthenes, and Isocrates. In physics, he chiefly followed Heraclitus; in ethics and politics, Socrates; and in metaphysics, Pythagoras.

After his death, two of the principal of his disciples, Xenocrates and Aristotle, continuing his office, and teaching, the one in the Academy, the other in the Lycæum, formed two sects, under different names, though in other respects the same; the one retaining the denomination of ACADEMICS, the other assuming that of PERIPATETICS. See these two articles.

Afterwards, about the time of the first ages of Christianity, the followers of Plato quitted the title of Academists, and took that of Platonists. It is supposed to have been at Alexandria, in Egypt, that they first assumed this new title, after having restored the ancient academy, and re-established Plato's sentiments; which had many of them been gradually dropped and laid aside. Porphyry, Plotin, Iamblichus, Proclus, and Plutarch, are those who acquired the greatest reputation among the Greek Platonists; Apuleius and Chalcidius, among the Latins; and Philo Judæus, among the Hebrews. The modern Platonists own Plotin the founder, or at least the reformer, of their sect.

The Platonic philosophy appears very consistent with the Mosaic; and many of the primitive fathers follow the opinions of that philosopher, as being favourable to Christianity. Justin is of opinion that there are many things in the works of Plato which this philosopher could not learn from mere natural reason; but thinks he must have learnt them from the books of Moses, which he might have read when in Egypt. Hence Numenius the Pythagorean expressly calls Plato the Attic Moses, and upbraids him with plagiarism; because he stole his doctrine concerning God and the world from the books of Moses. Theodoret says expressly, that he has nothing good and commendable concerning the Deity and his worship, but what he took from the Hebrew theology; and Clemens Alexandrinus calls him the Hebrew Philosopher. Gale is very particular in his proof of the point, that Plato borrowed his philosophy from the Scriptures, either immediately, or by means of tradition; and, besides the authority of the ancient writers, he brings some arguments from the thing itself. For example, Plato's confession, that the Greeks borrowed their knowledge of the one infinite God, from an ancient people, better and nearer to God than they; by which people, our author makes no doubt, he meant the Jews, from his account of the state of innocence; as, that man was born of the earth, that he was naked, that he enjoyed a truly happy state, that he conversed with brutes, &c. In fact, from an examination of all the parts of Plato's philosophy, physical, metaphysical, and ethical, this author finds, in every one, evident marks of its sacred original.

As to the manner of the creation, Plato teaches, that the world was made according to a certain exemplar, or idea, in the divine architect's mind. And all things, in the universe, in like manner, he shows, depend on the efficacy of internal ideas. This ideal world is thus explained by Didymus: "Plato supposes certain patterns, or exemplars, of all sensible things, which he calls ideas; and as there may be various impressions taken off from the same seal, so he says are there a vast number of natures existing from each idea." This idea he supposes to be an eternal essence, and to occasion the several things in nature to be such as itself is. And that most beautiful and perfect idea, which comprehends all the rest, he maintains to be the world.

Farther, Plato teaches that the universe is an intelligent animal, consisting of a body and a soul, which he calls the generated God, by way of distinction from what he calls the immutable essence, who was the cause of the generated God, or the universe.

According to Plato, there were two kinds of inferior and derivative gods; the mundane gods, all of which had a temporary generation with the world; and the supramundane eternal gods, which were all of them, one excepted, produced from that one, and dependent on it as their cause. Dr. Cudworth says, that Plato asserted a plurality of gods, meaning animated or intellectual beings, or dæmons, superior to men, to whom honour and worship are due; and applying the appellation to the sun, moon, and stars, and also to the earth. He asserts however, at the same time, that there was one supreme God, the self-originated being, the maker of the heaven and earth, and of all those other gods. He also maintains, that the Psyche, or universal mundane soul, which is a self-moving principle, and the immediate cause of all the motion in the world, was neither eternal nor self-existent, but made or produced by God in time; and above this self-moving Psyche, but subordinate to the Supreme Being, and derived by emanation from him, he supposes an immoveable Nous or intellect, which was properly the Demiurgus, or framer of the world.

The first matter of which this body of the universe was formed, he observes, was a rude indigested heap, or chaos: Now, adds he, the creation was a mixed production; and the world is the result of a combination of necessity and understanding, that is, of matter, which he calls necessity, and the divine wisdom; yet so that mind rules over necessity; and to this necessity he ascribes the introduction and prevalence both of moral and natural evil.

The principles, or elements, which Plato lays down, are fire, air, water, and earth. He supposes two heavens, the Empyrean, which he takes to be of a fiery nature, and to be inhabited by angels, &c; and the Starry heaven, which he teaches is not adamantine, or solid, but liquid and spirable.

With regard to the human soul, Plato maintained its transmigration, and consequently its future immortality and pre-existence. He asserted, that human souls are here in a lapsed state, and that souls sinning should fall down into these earthly bodies. Eusebius expressly says, that Plato held the soul to be ungenerated, and to be derived by emanation from the first cause.

His physics, or doctrine De Corpore, is chiefly laid down in his Timæus, where he argues on the properties of body in a geometrical manner; which Aristotle takes occasion to reprehend in him. His doctrine De Mente is delivered in his 10th book of laws, and his Parmenides.

St. Augustine commends the Platonic philosophy; and even says, that the Platonists were not far from Christianity. It is also certain that most of the celebrated fathers were Platonists, and borrowed many of their explanations of Scripture from the Platonic system. To account for this fact, it may be observed, that towards the end of the second century, a new sect of philosophers, called the modern, or later Platonics, arose of a sudden, spread with amazing rapidity through the greatest part of the Roman empire, swallowed up almost all the other sects, and proved very detrimental to Christianity.

The school of Alexandria in Egypt, instituted by Ptolemy Philadelphus, renewed and reformed the Platonic philosophy. The votaries of this system distinguished themselves by the title of Platonics, because they thought that the sentiments of Plato concerning the Deity and invisible things, were much more rational and sublime than those of the other philosophers. This new species of Platonism was embraced by such of the Alexandrian Christians as were desirous to retain, with the profession of the Gospel, the title, the dignity, and the habit of philosophers. Ammonius Saccas was its principal founder, who was succeeded by his disciple Plotinus, as this latter was by Porphyry, the chief of those formed in his school. From the time of Ammonius until the sixth century, this was almost the only system of philosophy publicly taught at Alexandria. It was brought into Greece by Plutarch, who renewed at Athens the celebrated academy, from whence issued many illustrious philosophers. The general principle on which this sect was founded, was, that truth was to be pursued with the utmost liberty, and to be collected from all the different systems in which it lay dispersed. But none that were desirous of being ranked among these new Platonists, called in question the main doctrines; those, for example, which regarded the existence of one God, the fountain of all things; the eternity of the world; the dependence of matter upon the Supreme Being; the nature of souls; the plurality of gods, &c.

In the fourth century, under the reign of Valentinian, a dreadful storm of persecution arose against the Platonists; many of whom, being accused of magical practices, and other crimes, were capitally convicted.

In the fifth century Proclus gave new life to the doctrine of Plato, and restored it to its former credit in Greece; with whom concurred many of the Christian doctors, who adopted the Platonic system. The Platonic philosophers were generally opposers of Christianity; but in the sixth century, Chalcidius gave the Pagan system an evangelical aspect; and those who, before it became the religion of the state, ranged themselves under the standard of Plato, now repaired to that of Christ, without any great change of their system.

Under the emperor Justinian, who issued a particular edict, prohibiting the teaching of philosophy at Athens, which edict seems to have been levelled at modern Platonism, all the celebrated philosophers of this sect took refuge among the Persians, who were at that time the enemies of Rome; and though they returned from their voluntary exile, when the peace was concluded between the Persians and Romans, in 533, they could never recover their former credit, nor obtain the direction of the public schools.

Platonism however prevailed among the Greeks, and was by them, and particularly by Gemistius Pletho, introduced into Italy, and established, under the auspices of Cosmo de Medicis, about the year 1439, who ordered Marsilius Ficinus to translate into Latin the works of the most renowned Platonists.

PLATONISTS, the followers of Plato; otherwise called Academics, from Academia, the name of the place that philosopher chose for his residence at Athens.

PLEIADES, an assemblage of seven stars in the neck of the constellation Taurus, the bull; though there are now only six of them visible to the naked eye. The largest of these is of the third magnitude, and called Lucido Pleiadum.—The Greeks fabled, that the name Pleiades was given to these stars from seven daughters of Atlas and Pleione, one of the daughters of Oceanus, who having been the nurses of Bacchus, were for their services taken up to heaven and placed there as stars, where they still shine. The meaning of which fable may be, that Atlas first observed these stars, and called them by the names of the daughters of his wife Pleione.

PLENILUNIUM, the full-moon.

PLENUM, in Physics, signifies that state of things, in which every part of space, or extension, is supposed to be full of matter; in opposition to a vacuum, which is a space devoid of all matter.—The Cartesians held the doctrine of an absolute plenum; namely on this principle, that the essence of matter consists in extension; and consequently, there being every where extension or space, there is every where matter: which is little better than begging the question.

PLINTH, in Architecture, a flat square member in form of a brick or tile; used as the foot or foundation of columns and pillars, &c.

PLOT, in Surveying, the plan or draught of any parcel of ground; as a field, farm, or manor, &c.

PLOTTING, in Surveying, the describing or laying down on paper, the several angles and lines, &c, of a tract of land, that has been surveyed and measured. Plotting is usually performed by two instruments, the protractor and plotting-scale; the former serving to lay off all the angles that have been measured and set down, and the latter all the measured lines. See these two instruments under their respective names.

PLOTTING *Scale*, a mathematical instrument chiefly used for the plotting of grounds in surveying, or setting off the lengths of the lines. It is either 6, 9, or 12 inches in length, and about an inch and half broad; being made of box-wood, brass, ivory, or silver; those of ivory are the neatest.

This instrument contains various scales or divided lines, on both sides of it. On the one side are a number of plane scales, or scales of equal divisions, each of a different number to the inch; as also scales of chords, for laying down angles; and sometimes even the degrees of a circle marked on one edge, answering to a centre marked on the opposite edge, by which means it serves also as a protractor. On the other side are several diagonal scales, of different sizes, or different divisions to the inch; serving to take off lines expressed by numbers to three dimensions, as units, tens, and hundreds; as also a scale of divisions which are the 100th parts of a foot. But the most useful of all the lines that can be laid upon this instrument, though not always done, is a line or plane scale upon the two opposite edges, made thin for that purpose. This is a very useful line in surveying; for by laying the instrument down upon the paper, with its divided edge along a line upon which are to be laid off several distances, for the places of off-sets, &c; these distances are all transferred at once from the instrument to the line on the paper, by making small marks or points against the respective divisions on the edge of the scale. See fig. 2 and 3, plates 26 and 27.

PLOTTING-*Table*, in Surveying, is used for a plane table, as improved by Mr. Beighton, who has obviated many inconveniences attending the use of the common plane table. See Philos. Trans. numb. 461.

PLOUGH, or PLOW, in Navigation, an ancient mathematical instrument, made of box or pear-tree, and used to take the height of the sun or stars, in order to find the latitude. This instrument admits of the degrees to be very large, and has been much esteemed by many artists; though now quite out of use.

PLOUGH-*Monday*, the first after Epiphany, or Jan. 6.

PLUMB-LINE, a term among artificers for a line perpendicular to the horizon.

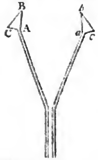
PLUMMET, PLUMB-RULE, or PLUMB-LINE, an instrument used by masons, carpenters, &c, to draw perpendiculars; in order to judge whether walls, &c, be upright, or planes horizontal, and the like.

PLUNGER, in Mechanics, a solid brass cylinder, used as a forcer in forcing-pumps.

PLUS, in Algebra, the affirmative or positive sign +, signifying more or addition, or that the quantity following it is either to be considered as a positive or affirmative quantity, or that it is to be added to the other quantities; so $4 + 6 = 10$, is read thus, 4 plus 6 is equal to 10. See AFFIRMATIVE *Sign*. The more early writers of Algebra, as Lucas de Burgo, Cardan, Tartaglia, &c, wrote the word mostly at full length: afterwards this was contracted or abbreviated, using one or two of its first letters; which initial was, by the Germans I think, corrupted to the present character +; which I find first used by Stifelius, printed in his Arithmetic.

PLUVIAMETER, a machine for measuring the quantity of rain that falls. There is described in the Philos. Trans. (numb. 473), by Robert Pickering, under the name of an Ombrameter, an instrument of this kind. It consists of a tin funnel *d*, whose surface is an inch square (fig. 6, plate 25); a flat board *aa*; and a glass tube *bb*, set into the middle of it in a groove; and an index with divisions *cc*; the board and tube being of any length at pleasure. The bore of the tube is about half an inch, which Mr. Pickering says is the best size. The machine is fixed in some free and open place, as the top of the house, &c.

The rain-gauge employed at the house of the Royal Society is described by Mr. Cavendish, in the Philos. Trans. for 1776, p. 384. The vessel which receives the rain is a conical funnel, strengthened at the top by a brass ring, 12 inches in diameter. The sides of the funnel and inner lip of the brass ring are inclined to the horizon, in an angle of above 65°; and the outer lip in an angle of above 50°; which are such degrees of steepness, that there seems no probability either that any rain which falls within the funnel, or on the inner lip of the ring, shall dash out, or that any which falls on the outer lip shall dash into the funnel. The annexed figure is a vertical section of the funnel, ABC and *abc* being the brass ring, BA and *ba* the inner lip, and BC and *bc* the outer.



In fixing pluviameters, care should be taken that the rain may have free access to them, without being impeded or overshaded by buildings, &c; and therefore the tops of houses are mostly to be preferred. Also when the quantities of rain collected in them, at different places, are compared together, the instruments ought to be fixed at the same height above the ground at both places; because at different heights the quantities are always different, even in the same place. And hence also, any register or account of rain in the pluviameter, ought to be accompanied with a note of the height above the ground the instrument is placed at. See *Quantity of* RAIN.

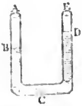
PNEUMATICS, that branch of natural philosophy which treats of the weight, pressure, and elasticity of the air, or elastic fluids, with the effects arising from them. Wolfius, instead of pneumatics, uses the term Aerometry.—This is a sister science to Hydrostatics; the one considering the air in the same manner as the other does water. And some consider pneumatics as a branch of mechanics; because it considers the air in motion, with the consequent effects.—For the nature and properties of air, see the article AIR, where they are pretty largely treated of.

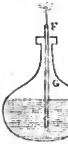
To which may be added the following, which respects more particularly the science of pneumatics, as contained in a few propositions, and their corollaries.

PROP. I. *The Air is a heavy fluid body, which surrounds and gravitates on all parts of the earth's surface.*

These properties of air are proved by experience. That it is a fluid, is evident from its easily yielding to any the least force impressed upon it, with little or no sensible resistance.—But when it is moved briskly, by any means, as by a fan, or a pair of bellows; or when any body is moved swiftly through it; in these cases we become sensible of it as a body, by the resistance it makes in such motions, and also by its impelling or blowing away any light substances. So that, being capable of resisting, or moving other bodies by its impulse, it must itself be a body, and be heavy, like all other bodies, in proportion to the matter it contains; and therefore it will press upon all bodies that are placed under it.—And being a fluid, it will spread itself over the entire surface of the earth; also like other fluids it will gravitate upon, and press every where upon the earth's surface.

The gravity and pressure of the air is also evident from many experiments. Thus, for instance, if water, or quicksilver, be poured into the tube ACE, and the air be suffered





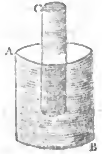
to press upon it, in both ends of the tube; the fluid will rest at the same height in both the legs: but if the air be drawn out of one end as E, by any means; then the air pressing on the other end A, will press down the fluid in this leg at B, and raise it up in the other to D, as much higher than at B, as the pressure of the air is equal to. By which it appears, not only that the air does really press, but also what the quantity of that pressure is equal to. And this is the principle of the barometer.

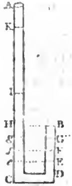
PROP. II. *The air is also an elastic fluid, being condensible and expansible. And the law it observes in this respect is this, that its density is always proportional to the force by which it is compressed.*

This property of the air is proved by many experiments. Thus, if the handle of a syringe be pushed inwards, it will condense the inclosed air into a less space; by which it is shown to be condensible. But the included air, thus condensed, will be felt to act strongly against the hand, and to resist the force compressing it more and more; and on withdrawing the hand, the handle is pushed back again to where it was at first. Which shows that the air is elastic.

Again, fill a strong bottle half full with water, and then insert a pipe into it, putting its lower end down near to the bottom, and cementing it very close round the mouth of the bottle. Then if air be strongly injected through the pipe, as by blowing with the mouth or otherwise, it will pass through the water from the lower end, and ascend up into the part before occupied by the air at G, and the whole mass of air become there condensed, because the water is not easily compressed into a less space. But on removing the force which injected the air at F, the water will begin to rise from thence in a jet, being pushed up the pipe by the increased elasticity of the air G, by which it presses on the surface of the water, and forces it through the pipe, till as much be expelled as there was air forced in; when the air at G will be reduced to the same density as at first, and, the balance being restored, the jet ceases.

Likewise, if into a jar of water AB, be inverted an empty glass tumbler C, or such like; the water will enter it, and

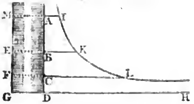




partly fill it, but not near so high as the water in the jar, compressing and condensing the air into a less space in the upper part C, and causing the glass to make a sensible resistance to the hand in pushing it down. But on removing the hand, the elasticity of the internal condensed air throws the glass up again.—All these showing that the air is condensible and elastic.

Again, to show the rate or proportion of the elasticity to the condensation; take a long slender glass tube, open at the top A, bent near the bottom or close end B, and equally wide throughout, or at least in the part BD (2d fig. above). Pour in a little quicksilver at A, just to cover the bottom to the bend at CD, and to stop the communication between the external air and the air in BD. Then pour in more quicksilver, and mark the corresponding heights at which it stands in the two legs: so, when it rises to H in the open leg AC, let it rise to E in the close one, reducing its included air from the natural bulk BD to the contracted space BE, by the pressure of the column He; and when the quicksilver stands at I and K, in the open leg, let it rise to F and G in the other, reducing the air to the respective spaces BF, BG, by the weights of the columns If, Kg. Then it is always found, that the condensations and elasticities are as the compressing weights, or columns of the quicksilver and the atmosphere together. So, if the natural bulk of the air BD be compressed into the spaces BE, BF, BG, or reduced by the spaces DE, DF, DG, which are $\frac{1}{4}$, $\frac{2}{4}$, $\frac{3}{4}$ of BD, or as the numbers 1, 2, 3; then the atmosphere, together with the corresponding column He, If, Kg, will also be found to be in the same proportion, or as the numbers 1, 2, 3: and then the weights of the quicksilver are thus, viz, He = $\frac{1}{3}$A, If = A, and Kg = 3A; where A denotes the weight of the atmosphere. Which shows that the condensations are directly as the compressing forces. And the elasticities are also in the same proportion, since the pressures in AC are sustained by the elasticities in BD.—From the foregoing principles may be deduced many useful remarks, as in the following corollaries.

Corol. 1. The space that any quantity of air is confined in, is reciprocally as the force that compresses it. So, the forces which confine a quantity of air in the cylindrical spaces AG, BG, CG, are reciprocally as the same, or reciprocally as the heights AD, BD, CD. And therefore, if to the two perpendicular lines AD, DH, as asymptotes, the hyperbola IKL be described, and the ordinates AI, BK, CL be drawn; then the forces which confine the air in the spaces AG, BG, CG, will be as the corresponding ordinates AI, BK, CL, since these are reciprocally as the abscisses AD, BD, CD, by the nature of the hyperbola.



Corol. 2. All the air near the earth is in a state of compression, by the weight of the incumbent atmosphere.

Corol. 3. The air is denser near the earth, than in high places; or denser at the foot of a mountain, than at the top of it. And the higher above the earth, the rarer it is.

Corol. 4. The spring or elasticity of the air, is equal to the weight of the atmosphere above it; and they will produce the same effects; since they are always sustained and balanced by each other.

Corol. 5. If the density of the air be increased, preserving the same heat or temperature; its spring or elasticity will also be increased, and in the same proportion.

Corol. 6. By the gravity and pressure of the atmosphere upon the surfaces of fluids, the fluids are made to rise in any pipes or vessels, when the spring or pressure within is diminished or taken off.

PROP. III. *Heat increases the elasticity of the air, and cold diminishes it. Or heat expands, and cold contracts and condenses the air.*

This property is also proved by experience.—Thus, tie a bladder very close, with some air in it; and lay it before the fire; then as it warms, it will more and more distend the bladder, and at last burst it, if the heat be continued and increased high enough. But if the bladder be removed from the fire, it will contract again to its former state by cooling.—It was on this principle that the first air-balloons were made by Montgolfier: for by heating the air within them, by a fire underneath, the hot air distends them to a size which occupies a space in the atmosphere whose weight of common air exceeds that of the balloon.

Also, if a cup or glass, with a little air in it, be inverted into a vessel of water; and the whole be heated over the fire, or otherwise: the air in the top will expand till it fill the glass, and expel the water out of it; and part of the air itself will follow, by continuing or increasing the heat. —Many other experiments to the same effect might be adduced, all proving the properties mentioned in the proposition.

Schol. Hence, when the force of the elasticity of the air is considered, regard must be had to its heat or temperature; the same quantity of air being more or less elastic, as its heat is more or less. And it has been found by experiment that its elasticity is increased at the following rate, viz, by the 435th part, by each degree of heat expressed by Fahrenheit's thermometer, of which there are 180 between the freezing and boiling point. It has also been found (Philos. Trans. 1777, pa. 560 &c), that water expands the 6666th part, with each degree of heat; and mercury the 9600th part by each degree. Moreover, the relative or specific gravities of these three substances, are as follow:

Air	1·232	when the barom. is at 30, and the thermom. at 55.
Water	1000	
Mercury	13600	

Also these numbers are the weights of a cubic foot of each, in the same circumstances of the barometer and thermometer.

PROP. IV. *The weight or pressure of the atmosphere, upon any base at the surface of the earth, is equal to the weight of a column of quicksilver of the same base, and its height between 28 and 31 inches.*

This is proved by the barometer, an instrument which measures the pressure of the air; the description of which see under its proper article. For at some seasons, and in some places, the air sustains and balances a column of mercury of about 28 inches; but at others, it balances a column of 29, or 30, or near 31 inches high; seldom in the extremes 28 or 31, but commonly about the means 29 or 30, and indeed mostly near 30. A variation which depends partly on the different degrees of heat in the air near the surface of the earth, and partly on the commotions and changes in the atmosphere, from winds and other causes, by which it is accumulated in some places, and depressed in others, being thereby rendered denser and heavier, or rarer and lighter; which changes in its state are almost continually happening in any one place. But the medium state is from 29½ to 30 inches.

Corol. 1. Hence the pressure of the atmosphere on every square inch at the earth's surface, at a medium, is very near 15 pounds avoirdupois. For, a cubic foot of mercury weighing nearly 13600 ounces, a cubic inch of it will weigh the 1728th part of it, or almost 8 ounces, or half a pound, which is the weight of the atmosphere for every inch of the barometer on a base of a square inch; and therefore 29½ inches, the medium height of the barometer, weighs almost 15 pounds, or rather 14¾lb very nearly.

Corol. 2. Hence also the weight or pressure of the atmosphere, is equal to that of a column of water from 32 to 35 feet high, or on a medium 33 or 34 feet high. For water and quicksilver are in weight nearly as 1 to 13·6; so that the atmosphere will balance a column of water 13·6 times higher than one of quicksilver; consequently $13·6 \times 30$ inches $=$ 408 inches or 34 feet, is near the medium height of water, or it is more nearly 33⅓ feet. And hence it appears that a common sucking pump will not raise water higher than about 34 feet. And that a syphon will not run if the perpendicular height of the top of it be more than 33 or 34 feet high.

Corol. 3. If the air were of the same uniform density, at every height, to the top of the atmosphere, as at the surface of the earth; its altitude would be about 5¼ miles at a medium. For the weights of the same volume of air and water, are nearly as 1·232 to 1000; therefore as 1·232 : 1000 : : 34 feet : 27600 feet, or 5¼ miles very nearly. And so high the atmosphere would be, if it were all of uniform density, like water. But, from its expansive and elastic quality, it becomes continually more and more rare the farther above the earth, in a certain proportion which will be treated of below.

Corol. 4. From this prop. and the last, it follows that the height is always the same, of a uniform atmosphere above any place, which shall be all of the uniform density with the air there, and of equal weight or pressure with the real height of the atmosphere above that place, whether it be at the same place at different times, or at any different places or heights above the earth; and that height is always about 27600 feet, or $5\frac{1}{4}$ miles, as found above in the 3d corollary. For, as the density varies in exact proportion to the weight of the column, it therefore requires a column of the same height in all cases, to make the respective weights or pressures. Thus, if W and w be the weights of atmosphere above any places, D and d their densities, and H and h the heights of the uniform columns, of the same densities and weights: Then $H \times D = W$, and $h \times d = w$; therefore $\frac{W}{D}$ or H is equal to $\frac{w}{d}$ or h; the temperature being the same.

PROP. V. *The density of the atmosphere, at different heights above the earth, decreases in such a proportion, that when the heights increase in arithmetical progression, the densities decrease in geometrical progression.*

Let the perpendicular line AP, erected on the earth, be conceived to be divided into a great number of very small parts A, B, C, D, &c, forming so many thin strata of air in the atmosphere, all of different density, gradually decreasing from the greatest at A: then the density of the several strata A, B, C, D, &c, will be in geometrical progression decreasing.

For, as the strata A, B, C, &c, are all of equal thickness, the quantity of matter in each of them, is as the density there; but the density in any one, being as the compressing force, is as the weight or quantity of matter from that place upward to the top of the atmosphere; therefore the quantity of matter in each stratum, is also as the whole quantity from that place upwards. Now if from the whole weight at any place as B, the weight or quantity in the stratum B be subtracted, the remainder will be the weight at the next higher stratum C; that is, from each weight subtracting a part which is proportional to itself, leaves the next weight; or, which is the same thing, from each density subtracting a part which is always proportional to itself, leaves the next density. But when any quantities are continually diminished by parts which are proportional to themselves, the remainders then form a series of continued proportionals; and consequently these densities are in geometrical progression. Thus, if the first density be D, and from each there be taken its nth part; then there remains its $\frac{n-1}{n}$ part, or the $\frac{m}{n}$ part, putting m for $n - 1$; and therefore the series of densities will be D, $\frac{m}{n}$ D, $\frac{m^2}{n^2}$ D, $\frac{m^3}{n^3}$ D, &c, $\frac{m}{n}$ being the common ratio of the series.

Schol. Because the terms of an arithmetical series are proportional to the logarithms of the terms of a geometrical series; therefore different altitudes above the earth's surface, are as the logarithms of the densities, or weights of air, at those altitudes. So that,

if D denote the density at the altitude A,
and d the density at the altitude a;
then A being as the logarithm of D,
and a as the logarithm of d,
the dif. of altitude $A - a$ will be as
the log. of D − log. of d, or as log. of $\frac{D}{d}$.

And if $A = 0$, or D the density at the surface of the earth, then any altitude above the surface a, is as the log. of $\frac{D}{d}$. Or, in general, the log. of $\frac{D}{d}$ is as the altitude of the one place above the other, whether the lower place be at the surface of the earth, or any where else.

And from this property is derived the method of determining the heights of mountains, and other eminences, by the barometer, which is an instrument that measures the weight or density of the air at any place. See BAROMETER. For by taking with this instrument, the pressure or density at the foot of a hill for instance, and again at the top of it, the difference of the logarithms of these two pressures, or the logarithms of their quotient, will be as the difference of altitude, or as the height of the hill; supposing the temperatures of the air to be the same at both places, and the gravity of air not altered by the different distances from the earth's centre.

See more on this head under the articles ATMOSPHERE and BAROMETER.

By the weight and pressure of the atmosphere, the effect and operations of pneumatic engines may be accounted for, and explained; such as syphons, pumps, barometers, &c. See each of these articles, also AIR.

PNEUMATIC *Engine*, the same as the AIR PUMP.

POCKET *Electrical Apparatus*.—This is a contrivance of Mr. William Jones, in Holborn, the form of which is represented in plate 28, fig. 4.

This small machine is capable of a tolerably strong charge, or accumulation of electricity, and will give a small shock to one, two, three, or a greater number of persons. A is the Leyden phial or jar that holds the charge. B is the discharger to discharge the jar when required without electrifying the person that holds it. C is a ribbon prepared in a peculiar manner so as to be excited, and communicate its electricity to the jar. D are two hair, &c, skin rubbers, which are to be placed on the first and middle fingers of the left hand.

To charge the Jar. Place the two finger-caps D on the first and middle finger of the left hand; hold the jar A at the same time, at the joining of the red and black on the outside between the thumb and first finger of the same hand; then take the ribbon in your right hand, and steadily and gently draw it upwards between the two rubbers D, on the two fingers; taking care at the same time, that the brass ball of the jar is kept nearly close to the ribbon, while it is passing through the fingers. By repeating this operation twelve or fourteen times, the electrical fire will pass into the jar which will become charged, and by placing the discharger C against it, as in the plate, you will see a sensible spark pass from the ball of the jar to that of the discharger. If the apparatus be dry and in good order, you will hear the crackling of the fire when the ribbon is passing through the fingers, and the jar will discharge at the distance represented in the figure.

To electrify a Person. You must desire him to take the jar in one hand, and with the other touch the knob of it: or, if diversion is intended, desire the person to smell at the knob of it, in expectation of smelling the scent of a rose or a pink; this last mode has occasioned it to be sometimes called the Magic Smelling Bottle.

POETICAL *Rising* and *Setting*. See RISING and SETTING.—The ancient poets, referring the rising and setting of the stars to that of the sun, make three kinds of rising and setting, viz, Cosmical, Acronical, and Heliacal. See each of these words in its place.

POINT, a term used in various arts and sciences.

POINT, in Architecture. Arches of the third Point, and Arches of the fourth Point. See ARCHES.

POINT, in Astronomy, is a term applied to certain parts or places marked in the heavens, and distinguished by proper terms. The four grand points or divisions of the horizon, viz, the east, west, north, and south, are called the Cardinal Points.—The zenith and nadir are the Vertical Points.—The points where the orbits of the planets cut the plane of the ecliptic, are called the Nodes.—The points where the ecliptic and equator intersect, are called the Equinoctial Points. In particular, that where the sun ascends towards the north pole is called the Vernal Point; and that where he descends towards the south, the Autumnal Point. —The highest and lowest points of the ecliptic are called the Solstitial Points. Particularly, the former of them the Estival or Summer Point; the latter, the Brumal or Winter Point.

POINTS, in Electricity, are those acute terminations of bodies which facilitate the passage of the electrical fluid either *from* or *to* such bodies. Mr. Jallabert was probably the first person who observed that a body pointed at one end, and round at the other, produced different appearances on the same body, according as the pointed or round end was presented to it. But Dr. Franklin first observed and evinced the whole effect of pointed bodies, both in drawing and throwing off electricity at greater distances than other bodies could do it; though he candidly acknowledges, that the power of points to throw off the electric fire was communicated to him by his friend Mr. Thomas Hopkinson.

Dr. Franklin electrified an iron shot, 3 or 4 inches in diameter, and observed that it would not attract a thread when the point of a needle, communicating with the earth, was presented to it; and he found it even impossible to electrify an iron shot when a sharp needle lay upon it. This remarkable property, possessed by pointed bodies, of gradually and silently receiving or throwing off the electric fluid, has been evinced by a variety of other familiar experiments. Thus, if one hand be applied to the outside coating of a large jar fully charged, and the point of a needle, held in the other, be directed towards the knob of the jar, and moved gradually near it, till the point of the needle touch the knob or ball, the jar will be entirely discharged, so as to give no shock at all, or one that is hardly sensible. In this case the point of the needle has gradually and silently drawn away the superabundant electricity from the electrified jar.

Further, if the knob of a brass rod be held at such a distance from the prime conductor, that sparks may easily escape from the latter to the former, while the machine is in motion; then if the point of a needle be presented, though at twice the distance of the rod from the conductor, no more sparks will be seen passing to the rod. When the needle is removed, the sparks will be seen; but on presenting it again, they will again disappear. So that the point of the needle draws off silently almost all the fluid, which is thrown by the cylinder or globe of the machine upon the prime conductor. This experiment may be varied, by fixing the needle upon the prime conductor with the point upward; and then, though the knob of a discharging rod, or the knuckle of the finger, be brought very near the prime conductor, and the excitation be very strong, little or no spark will be perceived.—The influence of points is also evinced in the amusing experiment, commonly called the electrical horse-race, and many others. See THUNDER-*house*.

The late Mr. Henly exhibited the efficacy of pointed bodies, by suspending a large bladder, well blown, and covered with gold, silver, or brass leaf, by means of gum-water, at the end of a silken thread 6 or 7 feet long, hanging from the ceiling of a room, and electrifying the bladder by giving it a strong spark with the knob of a charged bottle: on presenting to it the knob of a wire, it caused the bladder to move towards the knob, and when nearly in contact gave it a spark, thus discharging its electricity. By giving the bladder another charge, and presenting the point of a needle to it, the bladder was not attracted by the point, but rather receded from it, especially when the needle was suddenly presented towards it.

But experiments evincing the efficacy of pointed bodies for silently receiving or throwing off the electric fluid, may be infinitely diversified, according to the fancy or convenience of the electrician. It may be observed, that in the case of points throwing off or receiving electricity, a current of air is sensible at an electrified point, which is always in the direction of the point, whether the electricity be positive or negative. A fact which has been well ascertained by many electricians, and particularly by Dr. Priestley and Sig. Beccaria. The former contrived to exhibit the influence of this current on the flame of a candle, presented to a pointed wire, electrified negatively, as well as positively. The blast was in both cases alike, and so strong as to lay bare the greatest part of the wick, the flame being driven from the point; and the effect was the same whether the electric fluid issued out of the point or entered into it. He farther evinced this phenomenon by means of thin light vanes; and he found, as Mr. Wilson had before observed, that the vanes would not turn in vacuo, nor in a close unexhausted receiver where the air had no free circulation. And in much the same manner, Beccaria exhibited to sense the influence of the wind or current of air driven from points.

As to the *Theory* of the phenomena of points, these are accounted for in a variety of ways, by different authors, though perhaps by none with perfect satisfaction. See Franklin's writings on Electricity; Lord Mahon's Principles of Electricity, 1779; Beccaria's Artificial Electricity, 1776, pa. 331; and Priestley's History of Electricity, vol. 2, pa. 191, edit. 1775.

As to the *Application* of the doctrine of points; it may be observed that there is not a more important fact in the history of electricity, than the use to which the discovery of the efficacy of pointed bodies has been applied. Dr. Franklin, having ascertained the identity of electricity and lightning, was presently led to propose a cheap and easy method of securing buildings from the damage of lightning, by fixing a pointed metal rod higher than any part of the building, and communicating with the ground, or with the nearest water. And this contrivance was actually executed in a variety of cases; and has usually been thought an excellent preservative against the terrible effects of lightning.

Some few instances however having occurred, in which buildings have been struck and damaged, though provided with these conductors; a controversy arose with regard to their expediency and utility. In this controversy Mr. Benjamin Wilson took the lead, and Dr. Musgrave, and some few other electricians, the least acquainted with the subject, concurred with him in their opposition to pointed elevated conductors. These gentlemen allege, that every point, as such, solicits the lightning, and thus contributes not only to increase the quantity of every actual discharge, but also frequently to occasion a discharge when it might not otherwise have happened: whereas, say they, if instead of pointed conductors, those with blunted terminations were used, they would as effectually answer the purpose of conveying away the lightning safely, without the same tendency to increase or invite it. Accordingly Mr. Wilson, in a letter to the marquis of Rockingham (Philos. Trans. vol. 54, art. 44), expresses his opinion, that, in order to prevent lightning from doing mischief to high buildings, large magazines, and the like, instead of the elevated external conductors, that, on the inside of the highest part of such building, and within a foot or two of the top, it may be proper to fix a rounded bar of metal, and to continue it down along the side of the wall to any kind of moisture in the ground.

On the other hand, it is urged by the advocates for pointed conductors, that points, instead of increasing an actual discharge, really prevent a discharge where it would otherwise happen, and that blunted conductors tend to invite the clouds charged with lightning. And it seems to be a certain fact, that though a sharp point will draw off a charge of electricity silently at a much greater distance than a knob, yet a knob will be struck with a full explosion or shock, the charge being the same in both cases, at a greater distance than a sharp point.

The efficacy of pointed bodies for preventing a stroke of lightning, is ingeniously explained by Dr. Franklin in the following manner:—An eye, he says, so situated as to view horizontally the underside of a thunder-cloud, will see it very ragged; with a number of separate fragments or small clouds one under another; the lowest sometimes not far from the earth. These, as so many stepping-stones, assist in conducting a stroke between a cloud and a building. To represent these by an experiment, he takes two or three locks of fine loose cotton, and connects one of them with the prime conductor by a fine thread of 2 inches, another to that, and a third to the second, by like threads, which may be spun out of the same cotton. Then by turning the globe, all these locks will extend themselves towards the table, as the lower small clouds do towards the earth; but on presenting a sharp point, erect under the lowest, it will shrink up to the second, the second up to the first, and all together to the prime conductor, where they will continue as long as the point continues under them. May not, he adds, in like manner, the small electrified clouds, whose equilibrium with the earth is soon restored by the point, rise up to the main body, and by that means occasion so large a vacancy, as that the grand cloud cannot strike in that place? Letters, pa. 121.

Mr. Henly too, as well as several other persons, with a view of determining the question, whether points or knobs are to be preferred for the terminations of conductors, made several experiments, showing in a variety of instances, the efficacy of points in silently drawing off the electricity, and preventing strokes which would happen to knobs in the same situation. Philos. Trans. vol. 4, part 2, art. 18. See also THUNDER-*House*.

Indeed it has been universally allowed, that in cases where the quantity of electricity, with which thunder-clouds are charged, is small, or when they move slowly in their passage to and over a building, pointed conductors, which draw off the electrical fluid silently, within the distance at which rounded ends will explode, will gradually exhaust them, and thus contribute to prevent a stroke and preserve the buildings to which they are annexed.

But it has been said by those who are averse to the use of such conductors, that if clouds, of great extent, and highly electrified, should be driven directly over them with great velocity, or if a cloud hanging directly over buildings to which they are annexed, suddenly receives a charge by explosion from another cloud at a distance, so as to enable it instantly to strike into the earth, these pointed conductors must take the explosion; on account of their greater readiness to admit electricity at a much greater distance than those that are blunted, and in proportion to the difference of that striking distance, do mischief instead of good: and therefore, they add, that such pointed conductors, though they may be sometimes advantageous, are yet at other times prejudicial; and that, as the purpose for which conductors are fixed upon buildings, is not to protect them from one particular kind of clouds only, but if possible from all, it cannot be advisable to use that kind of conductors which, if they diminish danger on the one hand, will increase it on the other. Besides, it is alleged, that if pointed conductors are attended with any the slightest degree of danger, that danger must be considerably augmented by carrying them high up into the air, and by fixing them upon every angle of a building, and by making them project in every direction. Such is the reasoning of Dr. Musgrave: see his paper in the Philos. Trans. vol. 68, part 2, art 36.

Mr. Wilson too, dissenting from the report of a committee of the Royal Society, appointed to inspect the damage done by lightning to the house of the Board of Ordnance, at Purfleet, in 1777, was led to justify his dissent, and to disparage the use of pointed and elevated conductors, by means of a magnificent apparatus which he constructed, and with which he might produce effects similar to those that had happened in the case referred to the consideration and decision of the committee. With this view he procured a model of the Board-house at Purfleet, resembling it as nearly as possible in every essential appendage, and furnished with conductors of different lengths and terminations. And to construct a substitute for a cloud, he joined together the broad rims of 120 drums, forming together a cylinder of 155 feet in length, and above 16 inches in diameter; and this immense cylinder, of about 600 square feet of coated surface, was connected occasionally with one end of a wire 4800 feet long. As this bulky apparatus, representing the thunder-cloud, could not conveniently be put in motion, he contrived to accomplish the same end by moving the model of the building, with a velocity answering to that of the cloud, which he states, at a moderate computation, to be about 4 or 5 miles an hour. This apparatus was charged by a machine with one glass cylinder, about 10 or 11 feet from its nearest end; and the whole of the apparatus was disposed in the great room of the Pantheon, and applied to use in a variety of experiments. But it is impossible within the limits of this article to do justice to Mr. Wilson's experiments, or to the inferences which he deduced from them: we can only observe, that most of his experiments, in which the model of the house, which was passed swiftly under the artificial cloud, and having annexed to it either the pointed or blunt conductors at the same or different heights, were intended to show, that pointed conductors are struck at a greater distance, and with a higher elevation, than the blunted ones: and from all his experiments made with pointed and rounded conductors, provided the circumstances be the same in both, he infers, that the rounded ones are much the safer of the two; whether the lightning proceeds from one cloud or from several; that those are still safer which rise little or nothing above the highest part of the building; and that this safety arises from the greatest resistance exerted at the larger surface. See Philos. Trans. for 1778, pa. 232.

The committee of the Royal Society however, which was composed of nine of the most distinguished electricians in the kingdom, and to whom was referred the consideration of the most effectual method of securing the powder-magazines at Purfleet against the effects of lightning, express their united opinion, that elevated sharp rods, constructed and disposed in the manner which they direct, are preferable to low conductors terminated in rounded ends, knobs, or balls of metal; and that the experiments and reasonings, made and alleged to the contrary by Mr. Wilson, are inconclusive.

Mr. Nairne also, in order to obviate the objections of Mr. Wilson and others, and to vindicate the preference generally given to high and pointed conductors, constructed a much more simple apparatus than that of Mr. Wilson, with which he made a number of well-designed and well-conducted experiments, which appear to prove the superiority of the pointed conductor as far as it is capable of being proved by an artificial electrical apparatus. From these last experiments it appears, that though the point was struck by means of a swift motion of the artificial cloud, yet a small ball of 3 tenths of an inch diameter was struck further off than the point, and a larger ball at a much greater distance than either, even with the swiftest motion. Upon the whole, Mr. Nairne seems to be justified in preferring elevated pointed conductors; next to them, those that are pointed, though they rise but little above the highest part of a building; and after them, those that are terminated in a ball, and placed even with the highest part of the building. See Philos. Trans. 1778, pa. 823.

On the other part, Dr. Musgrave, not yet satisfied, gave in another paper, being "Reasons for dissenting from the Report of the Committee appointed to consider of Mr. Wilson's Experiments; including Remarks on some Experiments exhibited by Mr. Nairne;" which is inserted, by mistake, before Mr. Nairne's paper, being at pa. 801 of the same volume.

And further, Mr. Wilson has another paper, on the same subject, at pa. 999 of the same vol. of Philos. Trans. for 1778, entitled, "New Experiments upon the Leyden Phial, respecting the termination of conductors;" repeating and asserting his former objections and reasonings.

In the Philos. Trans. too, for 1779, pa. 454, Mr. William Swift has a paper, further prosecuting this subject; making various experiments with simple and ingenious machinery, with models of houses and clouds, and with various kinds of conductors. From the experiments he infers in general, that "the whole current of these experiments tends to show the preference of points to balls, in order to diminish and draw off the electric matter when excited, or to prevent it from accumulating; and consequently the propriety or even necessity of terminating all conductors with points, to make them useful to prevent damage to buildings from lightning. Nay the very construction of all electrical machines, in which it is necessary to round all the parts, and to avoid making edges and points which would hinder the matter from being excited, will, I imagine, on reflection, be another corroborating proof of the result of the experiments themselves."

There were other communications made to the Royal Society on the important subject of conductors, some of which were received, and others rejected. On the whole, this contest turned out one of the most extraordinary that ever was agitated in the Society; producing the most remarkable disputes, differences, and strange consequences, that ever the Society experienced since it had existence; consequences which manifested themselves in various instances for many years after, and which continue to this very day. All which, with the various secret springs and astonishing intrigues, may probably be given to the public on some other occasion.

Point, in Geometry, according to Euclid, is that which has no parts, or is indivisible; being void of all extension, both as to length, breadth, and depth.

This is what is otherwise called the Mathematical Point, being the intersection of two lines, and is only conceived by the imagination; yet it is in this that all magnitude begins and ends; the extremes of a line being points; the extremes of a surface, lines; and the extremes of a solid, surfaces. And hence some define a point, the inceptive of magnitude.

Proportion of Mathematical Points. It is a popular maxim, that all infinites are equal; yet is the maxim false, whether of quantities infinitely great, or infinitely little. Dr. Halley, and others have shown that there are infinite quantities which are in a finite proportion to each other; and some that are infinitely greater than others. See Infinite *Quantity*.

And the same is shown by Mr. Robarts, of infinitely small quantities, or mathematical Points. He demonstrates, for instance, that the points of contact between circles and their tangents, are in the subduplicate ratio of the diameters of the circles; that the point of contact between a sphere and a plane is infinitely greater than between a circle and a line; and that the points of contact in spheres of different magnitudes, are to each other as the diameters of the spheres. Philos. Trans. vol. 27, pa. 470.

Conjugate Point, is used for that point into which the conjugate oval, belonging to some kind of curves, vanishes. Maclaurin's Algebra, pa. 308.

Point *of Contrary Flexure*, &c. See Inflexion, Retrogradation or Retrogression, &c, of curves.

Points *of the Compass*, or *Horizon*, &c, in Geography and Navigation, are the points of division when the whole circle, quite around, is divided into 32 equal parts. These points are therefore at the distance of the 32d part of the circle, or 11°15′, from each other; hence 5° 37′½ is the distance of the half points, and 2° 48′¾ is the distance of the quarter points. See COMPASS. The principal of these are the four cardinal points, east, west, north, and south.

Point is also used for a cape or headland, jutting out into the sea.—The seamen say two points of land are one in another, when they are in a right line, the one behind the other.

POINT, in Optics. As the

POINT *of Concourse* or *Concurrence*, is that in which converging rays meet; and is usually called focus.

POINT of *Dispersion*, *Incidence*, *Reflection*, *Refraction*, and *Radiant* POINT. See these several articles.

POINT, in Perspective, is a term used for various parts or places, with regard to the perspective plane. As, the

POINT *of Sight*, or *of the Eye*, called also the Principal Point, is the point on a plane where a perpendicular from the eye meets it. See PERSPECTIVE. Some authors, however, by the Point of Sight, or Vision, mean the point where the eye is actually placed, and where all the rays terminate. See PERSPECTIVE.

POINT *of Distance*, is a point in a horizontal line, at the same distance from the principal point as the eye is from the same. See PERSPECTIVE.

Third POINT, is a point taken at discretion in the line of distance, where all the diagonals meet that are drawn from the divisions of the geometrical plane.

Objective POINT, is a point on a geometrical plane, whose representation on the perspective plane is required.

Accidental Point, and *Visual* POINT. See ACCIDENTAL and VISUAL.

POINT *of View*, with regard to Building, Painting, &c, is a point at a certain distance from a building, or other object, where the eye has the most advantageous view or prospect of the same. And this point is usually at a distance equal to the height of the building.

POINT, in Physics, is the smallest or least sensible object of sight, marked with a pen, or point of a compass, or the like. This is popularly called a Physical point, and of such does all physical magnitude consist.

POINT-BLANC, *Point-Blank*, in Gunnery, denotes the horizontal or level position of a gun, or having its muzzle neither elevated nor depressed. And the point-blanc range, is the distance the shot goes, before it strikes the level ground, when discharged in the horizontal or point-blanc direction. Or sometimes this means the distance the ball goes horizontally in a straight-lined direction.

POINTING, in Artillery and Gunnery, is the laying a piece of ordnance in any proposed direction, either horizontal, or elevated, or depressed, to any angle. This is usually effected by means of the gunner's quadrant, which, being applied to, or in, the muzzle of the piece, shows by a plummet the degree of elevation or depression.

POINTING, in Navigation, is the marking on the chart in what point, or place, the vessel is.—This is done by means of the latitude and longitude, after these are known, or found by observation or computation. Thus, draw a line, with a pencil, across the chart according to the latitude; and another across the other way according to the longitude; then the intersection of these two lines, is the point or place on the chart where the ship is; which is then marked black with a pen, and the pencil lines rubbed out. From the point or place, thus found, the chart readily shows the direct distance and course run, as also that still to run to the intended port, &c.

POLAR, something that relates to the poles of the world: as polar virtue, polar tendency.

POLAR *Circles*, are two lesser circles of the sphere, or globe, one about each pole, and at the same distance from it as is equal to the sun's greatest declination or the obliquity of the ecliptic; that is, at present 23° 28′.—The space included within each polar circle, is the frigid zone; and to every part of this space, the sun never sets at some time of the year, and never rises at another time; each of these being a longer duration as the place is nearer the pole.

POLAR *Dials*, are such as have their planes parallel to some great circle passing through the poles, or to some one of the hour-circles; so that the pole is neither elevated above the plane, nor depressed below it.—This dial, therefore, can have no centre; and consequently its style, substyle, and hour-lines, are parallel.—This will therefore be an horizontal dial to those who live at the equator.

POLAR *Projection*, is a representation of the earth, or heavens, projected on the plane of one of the polar circles.

POLAR *Regions*, are those parts of the earth which lie near the north and south poles.

POLARITY, the quality of a thing having poles, or pointing to, or respecting some pole: as the magnetic needle, &c.—By heating an iron bar, and letting it cool again in a vertical position, it acquires a polarity, or magnetic virtue: the lower end becoming the north pole, and the upper end the south pole. But iron bars acquire a polarity by barely continuing a long time in an erect position, even without heating them. Thus, the upright iron bars of some windows, &c, are often found to have poles: Nay, an iron rod acquires a polarity, by the mere holding it erect; the lower end, in that case, attracting the south end of a magnetic needle; and the upper, the north end. But these poles are mutable, and shift with the situation of the rod.—Some modern writers, particularly Dr. Higgins, in his Philosophical Essay concerning Light, have maintained the polarity of the parts of matter, or that their simple attractions are more forcible in one direction, or axis of each atom, than in any other.

POLES, in Astronomy, the extremities of the axis on which the whole sphere of the world revolves; or the points on the surface of the sphere through which the axis passes. These are on every side at the distance of a quadrant, or 90°, from every point of the equinoctial, and are called, by way of eminence, the poles of the world. That which is visible to us in Europe, or raised above our horizon, is called the Arctic or North Pole; and its opposite one, the Antarctic or South Pole.

POLES, in Geography, are the extremities of the earth's axis; or the points on the surface of the earth through which the axis passes. Of which, that elevated above our horizon is called the Arctic or North Pole; and the opposite one, the Antarctic or South Pole.

In consequence of the situation of the poles, with the inclination of the earth's axis, and its parallelism during the annual motion of our globe round the sun, the poles have only one day and one night throughout the year, each being half a year in length. And because of the obliquity with which the rays of the sun fall upon the polar regions, and the great length of the night in the winter season, it is commonly supposed the cold is so intense, that those parts of the globe which lie near the poles have never been fully explored, though the attempt has been repeatedly made by the most celebrated navigators. And yet Dr. Halley was of opinion, that the solstitial day, at the pole, is as hot as at the equator when the sun is in the zenith; because all the 24 hours of that day under the pole the sun-beams are inclined to the horizon in an angle of 23° 28′; whereas at the equator, though the sun becomes vertical, yet he shines no more than 12 hours, being absent the other 12 hours: and besides, that during 3 hours 8 minutes of the 12 hours which he is above the horizon there, he is not so much elevated as at the pole. Experience however seems to show that this opinion and reasoning of Dr. Halley are not well founded: for in all the parts of the earth that we know, the middle of summer is always the less hot the farther the place is from the equator, or the nearer it is to the pole.

The great object for which navigators have ventured themselves in the frozen seas about the north pole, was to find out a more quick and ready passage to the East Indies. And this has been attempted three several ways: one by coasting along the northern parts of Europe and Asia, called the north-east passage; another, by sailing round the northern part of the American continent, called the north-west passage; and the third, by sailing directly over the pole itself.

The possibility of succeeding in the north-east was for a long time believed; and in the last century many navigators, particularly the Hollanders, attempted it with great fortitude and perseverance. But it was always found impossible to surmount the obstacles which nature had thrown in the way; and subsequent attempts have in a manner demonstrated the impossibility of ever sailing eastward along the northern coast of Asia. The reason of this impossibility is, that in proportion to the extent of land, the cold is always greater in winter, and *vice versa*. This is the case even in temperate climates; but much more so in those frozen regions when the sun's influence, even in summer, is but small. Hence, as the continent of Asia extends a vast way from west to east, and has besides the continent of Europe joined to it on the west, it follows, that about the middle part of that tract of land the cold should be greater than any where else. Experience has determined this to be fact; and it now appears, that about the middle of the northern part of Asia, the ice never thaws; neither have even the hardy Russians and Siberians themselves been able to overcome the difficulties they meet with in that part of their voyages.

With regard to the north-west passage, the same difficulties occur as in the other. According to Captain Cook's voyage, it appears that if there is any strait which divides the continent of America into two, it must lie in a higher latitude than 70°, and consequently be perpetually frozen up. And therefore if a north-west passage can be found, it must be by sailing round the whole American continent, instead of seeking a passage through it, which some have supposed to exist in the bottom of Baffin's Bay. But the extent of the American continent to the northward is yet unknown; and there is a possibility of its being joined to that part of Asia between the Piasida and Chatanga, which has never yet been circumnavigated. Indeed a rumour has lately gone abroad of some remarkable inlet being observed on the western coast of North America, which it is guessed may possibly lead to some communication with the eastern side, by the lakes, or a passage into Hudson's Bay: but there seems little or no probability of any success this way, in which many fruitless attempts have been made at various times. It remains therefore to consider, whether there is any probability of attaining the wished-for passage by sailing directly north, between the eastern and western continents.

The late celebrated mathematician, Mr. Maclaurin, was so fully persuaded of the practicability of passing by this way to the South and Indian seas, that he used to say, if his other avocations would permit, he would undertake the voyage of trial, even at his own expense. The practicability of this method, which would lead directly to the pole itself, has also been ingeniously supported by Mr. Daines Barrington, in some tracts published in the years 1775 and 1776, in consequence of the unsuccessful attempt made by captain Phipps in the year 1773, to reach a higher northern latitude than 81°. Mr. Barrington instances a great number of navigators who have reached very high northern latitudes; nay, some who have been at the pole itself, or gone beyond it. From all which he concludes, that if the voyage be attempted at a proper time of the year, there would not be any great difficulty in reaching the pole. Those vast pieces of ice which commonly obstruct the navigators, he thinks, proceed from the mouths of the great Asiatic rivers which run northward into the frozen ocean, and are driven eastward and westward by the currents. But, though we should suppose them to come directly from the pole, still our author thinks that this affords an undeniable proof that the pole itself is free from ice; because, when the pieces leave it, and come to the southward, it is impossible that they can at the same time accumulate at the pole.

The Altitude or Elevation of the POLE, is an arch of the meridian intercepted between the pole and the horizon of any place, and is equal to the latitude of the place.

To observe the Altitude of the POLE. With a quadrant, observe both the greatest and least meridian altitude of the pole star. Then half the sum of the two altitudes, will be the height of the pole, or the latitude of the place; and half the difference of the same will be the distance of the star from the pole. But, for accuracy, the observed altitudes should be corrected on account of refraction, before their sum or difference is taken. See REFRACTION.

POLE, in Spherics, or the pole of a great circle, is a point on the sphere equally distant from every part of the circumference of the great circle; or a point 90° distant from the circumference of any part of it.—The zenith and nadir are the poles of the horizon; and the poles of the equator are the same with those of the sphere or globe.

POLES, in Magnetism, are two points in a loadstone, corresponding to the poles of the world; one pointing to the north, and the other to the south. If the stone be broken in ever so many pieces, every fragment will still have its two poles. And if a magnet be bisected by a plane perpendicular to the axis; the two points before joined will become opposite poles, one in each segment. —In touching a needle, &c, with a magnet, that part intended for the north end must be touched with the south pole of the magnet; and that intended for the south end, with the north pole; for the poles of the needle become contrary to those of the magnet.—A piece of iron acquires a polarity by only holding it upright; though its poles are not fixed, but shift, and are inverted as the iron is. Fire destroys all fixed poles; but it strengthens the mutable ones.

Dr. Gilbert says, the end of a rod being heated, and left to cool pointing northward, it becomes a fixed north pole;

if southward, a fixed south pole. When the end is cooled while held downward, it acquires rather more magnetism than if cooled horizontally towards the north. But the best way is to cool it a little inclined to the north. Repeating the operations of heating and cooling does not increase the effect.

Dr. Power says, if a rod be held northwards, and the north end be hammered in that position, it will become a fixed north pole; and contrarily if the south end be hammered. The heavier the blows are, cæteris paribus, the stronger will the magnetism be; and a few hard blows have as much effect as a great number. And what is said of hammering, is to be likewise understood of filing, grinding, sawing, &c; nay, a gentle rubbing, when long continued, will produce poles.

Old punches and drills have all fixed north poles; because they are almost constantly used downwards. New drills have either mutable poles, or weak north ones. Drilling with such a one southward horizontally, it is a chance if you produce a fixed south pole; much less if you drill south downwards; but by drilling south upwards, you always make a fixed south pole. Mr. Ballard says, that in 6 or 7 drills, made in his presence, the bit of each became a north pole, merely by hardening.—A weak fixed pole may degenerate into a mutable one in a day, or even in a few minutes, by holding it in a position contrary to its pole. The loadstone itself will not make a fixed pole in every piece of iron: if the iron be thick, it is necessary that it have some considerable length.

Pole *of a Glass*, in Optics, is the thickest part of a convex glass, or the thinnest part of a concave one; being the same as what is otherwise called the vertex of the glass; and which, when truly ground, is exactly in the middle of its surface.

Pole, or *Rod*, in Surveying, is a lineal measure containing 5½ yards, or 16½ feet.—The square of it is called a square pole; but more usually a perch, or a rod.

Pole-Star, is a star of the 2d magnitude near the north pole, in the end of the tail of ursa minor, or the Little Bear. Its mean place in the heavens for the beginning of 1810, was as follows: viz,

Right ascension - -	13°	36′	15″
Annual variat. in ditto -	0	3	8
Declination - -	88	17	41
Annual variat. in ditto -	0	0	$19\frac{6}{10}$

The proximity of this star to the pole, on which account it is always above the horizon in these northern latitudes, makes it very useful in navigation, &c, for determining the meridian line, the elevation of the pole, and consequently the latitude of the place, &c.

POLEMOSCOPE, in Optics, an oblique kind of prospective glass, contrived for the seeing of objects that do not lie directly before the eye. It was invented by Hevelius, in 1637. See Opera *Glass*.

POLITICAL *Arithmetic*, the application of arithmetical calculations to political uses and subjects; such as the public revenues, the number of people, the extent and value of lands, taxes, trade, commerce, or whatever relates to the power, strength, riches, &c, of a nation or commonwealth. Or, as Davenant concisely defines it, the art of reasoning by figures, upon things relating to government. The chief authors who have attempted calculations of this kind, are, Sir William Petty, Major Graunt, Dr. Halley, Dr. Davenant, Mr. King, Dr. Price, M. Kerseboom, and M. de Parcieux.

Sir William Petty, among many other articles, states that, in his time, the people in England were about 6 millions, and their annual expense about 7*l.* each; that the rent of the lands was about 8 millions, and the interests and profits of the personal estates as much; that the rent of the houses in England was 4 millions, and the profits of the labour of all the people 26 millions yearly; that the corn used in England, at 5*s.* the bushel for wheat, and 2*s.* 6*d.* for barley, amounts to 10 millions per annum; that the navy of England required 36,000 men to man it, and the trade and other shipping about 48,000; that the whole number of people in England, Scotland, and Ireland, together, were about 9 millions and a half; and those in France about 13 millions and a half; and in the whole world about 350 millions; also that the whole cash of England, in current money, was then about 6 millions sterling. See his Political Arith. p. 74, &c.

Dr. Davenant gives some good reasons why many of Sir W. Petty's numbers are not to be entirely depended on; and advances others of his own, founded on the observations of Mr. Greg. King. Some of the particulars are, that the land of England is 39 millions of acres; that the number of people in London was about 530,000, and in all England five millions and a half, increasing 9000 annually, or about the 600th part; the yearly rent of the lands 10 millions, and that of the houses 2 millions; the produce of all kinds of grain 9 millions. Davenant's Essay on the probable methods, &c, in his works, vol. 6.

Major Graunt, in his observations on the bills of mortality, computes, that there are 39,000 square miles of land in England, or 25 million acres in England and Wales, and 4,600,000 persons, making about 5 acres and a half to each person; that the people of London were 640,000; and states the several numbers of persons living at the different ages.

Sir William Petty, in his discourse about duplicate proportion, further states, that it is found by experience, that there are more persons living between 16 and 26 than of any other age; and from thence he infers, that the square roots of every number of men's ages under 16, whose root is 4, show the proportion of the probability of such persons reaching the age of 70 years: thus, the probability of reaching that age by persons of the

ages of 16, 9, 4, and 1,
are as 4, 3, 2, 1, respectively.

Also that the probabilities of their order of dying, at ages above that, are as the square roots of the ages: thus, the probabilities of the order of dying first,

of the ages 16, 25, 36, &c,
are as the roots 4, 5, 6, &c,

that is, the odds are 5 to 4 that a person of 25 dies before one of 16, and so on, declining up to 70 years of age.

Dr. Halley has made a very exact estimation of the degrees of mortality of mankind, from a curious table of the births and burials, at the city of Breslau, in Silesia; with an attempt to ascertain the price of annuities upon lives, and many other curious particulars. See the Philos. Trans. vol. 17, pa. 596. Another table of this kind is given by Simpson, for the city of London; and several by Price, Morgan and Baily, for many different places.

Mr. Kerseboom, of Holland, has many and curious calculations and tables of the same kind. From his observations on the births of the people in England, it appears, that the number of males born, is in proportion to that of the females, as 18 to 17; and that of the inhabitants living in Holland are in the same proportion.

Dr Brackenridge has given an estimate of the number of people in England, formed both from the number of houses, and also from the quantity of bread consumed. On the former principle, he finds the number of houses in England and Wales to be about 900,000; and, allowing 6 persons to each house, the number of people near 5 millions and a half. And on the latter principle, estimating the quantity of corn consumed at home at 2 millions of quarters, and 3 persons to every quarter of corn, makes the number of people 6 millions. See Philos. Trans. vol. 49, art. 45 and 113.

Dr. Derham, from a great number of registers of places, finds the proportions of the marriages to the births and burials; and Dr. Price has done the same for still more places; the mediums of all which are,

	Marriages to Births, as
Dr. Derham - -	1 to 4·7
Dr. Price - -	1 to 3·9

See Philos. Trans. No. 480; also Dr. Price's Observations on Reversionary Payments; and the articles of this Dictionary, Expectation *of Life*, Life-*Annuities*, Mortality, Population, &c.

POLLUX, in Astronomy, the hind twin, or the posterior part of the constellation Gemini.

Pollux is also a fixed star of the second magnitude, in the constellation Gemini, or the Twins. See Castor and *Pollux*, also Gemini.

POLYACOUSTICS, instruments contrived to multiply sounds, as polyscopes or multiplying glasses do the images of objects.

POLYEDRON. See Polyhedron.

POLYGON, in Geometry, a figure of many sides; and consequently of many angles also; for every figure has as many sides as angles. If the angles be all equal among themselves, the polygon is said to be a regular one; otherwise, it is irregular. Polygons also take particular names according to the number of their sides; thus a Polygon of

3 sides is called a trigon,
4 sides - a tetragon,
5 sides - a pentagon,
6 sides - a hexagon, &c;

and a circle may be considered as a polygon of an infinite number of small sides, or as the limit of the polygons.

Polygons have various properties, as below:

1. Every polygon may be divided into as many triangles as it hath sides.

2. The angles of any polygon taken together, make twice as many right angles, wanting 4, as the figure hath sides. Thus, if the polygon has 5 sides; the double of that is 10, from which subtracting 4, leaves 6 right angles, or 540 degrees, which is the sum of the 5 angles of the pentagon. And this property, as well as the former, belongs to both regular and irregular polygons.

3. Every regular polygon may be either inscribed in a circle, or described about it. But not so of the irregular ones, except the triangle, and another particular case as in the following property: An equilateral figure inscribed in a circle, is always equiangular.—But an equiangular figure inscribed in a circle is not always equilateral, but only when the number of sides is odd. For if the sides be of an even number, then they may either be all equal; or else half of them may be equal, and the other half equal to each other, but different from the former half, the equals being placed alternately.

4. Every polygon, circumscribed about a circle, is equal to a right-angled triangle, of which one leg is the radius of the circle, and the other the perimeter or sum of all the sides of the polygon. Or the polygon is equal to half the rectangle under its perimeter and the radius of its inscribed circle, or the perpendicular from its centre upon one side of the polygon. Hence, the area of a circle being less than that of its circumscribing polygon, and greater than that of its inscribed one, the circle is the limit of the inscribed and circumscribed polygons; in like manner the circumference of the circle is the limit between the perimeters of the said polygons; consequently the circle is equal to a right-angled triangle, having one leg equal to the radius, and the other leg equal to the circumference; and therefore its area is found by multiplying half the circumference by half the diameter. In like manner, the area of any polygon is found by multiplying half its perimeter by the perpendicular demitted from the centre upon one side.

5. In my Mensuration, pa. 15 &c, is given the geometrical construction of several polygons; by which it appears that, as the regular trigon, square, and pentagon, can be inscribed geometrically in a circle; and as an arc may be always bisected geometrically; therefore any polygon whose numbers of sides is expressed by 2^n, 3.2^n, or 5.2^n, may be inscribed in a given circle by the scale and compasses only. And it has lately been shown that a polygon, the number of whose sides is a prime number of the form $2^n + 1$, may also be inscribed geometrically in a circle, a problem that was far from being thought possible, till M. Gauss published his celebrated work entitled Disquisitiones Arithmeticæ, in which he has given a complete solution of this problem; it is however too complex to introduce in this place, and little suited to practical purposes. See Prime Number.

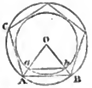
6. But though we cannot inscribe geometrically any regular polygon whatever in a circle, we have a practical method of performing it, by means of the known measure of the angles, some examples of which may be seen in the following table, which exhibits the most remarkable particulars in all the polygons, up to the dodecagon of 12 sides; viz, the angle at the centre AOB, the angle of the polygon C or CAB or double of OAB, and the area of the polygon when each side AB is 1. (See the following figure.)

No. of sides.	Name of polygon.	Ang. O. at cent.	Ang. C. of polygon.	Area.
3	Trigon	120	60	0·4330127
4	Tetragon	90	90	1·0000000
5	Pentagon	72	108	1·7204774
6	Hexagon	60	120	2·5980762
7	Heptagon	$51\frac{3}{7}$	$128\frac{4}{7}$	3·6339124
8	Octagon	45	135	4·8284271
9	Nonagon	40	140	6·1818242
10	Decagon	36	144	7·6942088
11	Undecagon	$32\frac{8}{11}$	$147\frac{3}{11}$	9·3656399
12	Dodecagon	30	150	11·1961524

By means of the numbers in this table, any polygons may be constructed, or their areas found: thus, (1st) *To inscribe a Polygon in a given Circle.* At the centre make the angle O equal to the angle at the centre of the proposed polygon, found in the 3d column of the table, the legs cutting the circle in A and B; and join A and B which will be one side of the polygon. Then take AB between the compasses, and apply it continually round the circumference, to complete the polygon.

(2d) *Upon the given Line* AB *to describe a regular Polygon.* From the extremities draw the two lines AO and BO, making the angles A and B each equal to half the angle of the polygon, found in the 4th column of the table, and their intersection O will be the centre of the circumscribed circle: then apply AB continually round the circumference as before.

(3d) *To describe a Polygon about a given Circle.*—At the centre O make the angle of the centre as in the 1st art. its legs cutting the circle in *a* and *b*: join *ab*, and parallel to it draw AB to touch the circle: and meeting O*a* and O*b* produced in A and B: with the radius OA, or OB, describe a circle, and around its circumference apply continually AB, which will complete the polygon as before.



(4th) *To find the Area of any regular Polygon*—Multiply the square of its side by the tabular area, found on the line of its name in the last column of the table, and the product will be the area. Thus, to find the area of the trigon, or equilateral triangle, whose side is 20. The square of 20 being 400 multiply the tabular area ·4330127 by 400, and the product 173·20508 will be the area.

7. There are also several curious algebraical theorems for inscribing polygons in circles, or finding the chord of any proposed part of the circumference, which is the same as angular sections. These kinds of sections, or parts and multiples of arcs, were first treated of by Vieta, as shown in the Introduction to my Log. pa. 9, and since pursued by several other mathematicians, in whose works they are usually to be found.

POLYGON, in Fortification, denotes the figure or perimeter of a fortress, or fortified place. This is either Exterior or Interior.

Exterior POLYGON is the perimeter or figure formed by lines connecting the points of the bastions to one another, quite round the work. And

Interior POLYGON, is the perimeter or figure formed by lines connecting the centres of the bastions, quite around.

Line of POLYGONS, is a line on some sectors, containing the homologous sides of the first nine regular polygons inscribed in the same circle; viz, from an equilateral triangle to a dodecagon.

POLYGONAL *Numbers*, are the continual or successive sums of numbers in arithmetical progression, beginning at 1, and regularly increasing; being called polygonals, because the number of points in them may be arranged in the form of the several polygonal figures in geometry, as is illustrated under the article FIGURATE *Numbers*; which see.

The several kinds of polygonal numbers, viz, the triangles, squares, pentagons, hexagons, &c, are formed from the addition of the terms of the arithmetical series, having respectively their common difference 1, 2, 3, 4, &c; viz, if the common difference of the arithmeticals be 1, the sums of their terms will form the triangles; if 2, the squares; if 3, the pentagons; if 4, the hexagons, &c. Thus:

{ Arith. Progres.	1,	2,	3,	4,	5,	6,	7.
{ Triang. Nos.	1,	3,	6,	10,	15,	21,	28.
{ Arith. Progres.	1,	3,	5,	7,	9,	11,	13.
{ Square Numbers	1,	4,	9,	16,	25,	36,	49.
{ Arith. Progres.	1,	4,	7,	10,	13,	16,	19.
{ Pentagonal Nos.	1,	5,	12,	22,	35,	51,	70.
{ Arith. Progres.	1,	5,	9,	13,	17,	21,	25.
{ Hexagonal Nos.	1,	6,	15,	28,	45,	66,	91.

The *Side* of a polygonal number is the number of points in each side of the polygonal figure when the points in the number are ranged in that form. And this is also the same as the number of terms of the arithmeticals that are added together in composing the polygonal number.

The *Angles*, or Numbers of Angles, are the same as those of the figure from which the number takes its name. So the angles of the triangular numbers are 3, of the square ones 4, of the pentagonals 5, of the hexagonals 6, and so on. Hence, the angles are 2 more than the common difference of the arithmetical series from which any rank of polygonals is formed: so the arithmetical series has for its common difference the number 1 or 2 or 3 &c as follows, viz, 1 in the triangles, 2 in the squares, 3 in the pentagons, &c; and, in general, if a be the number of angles in the polygon, then $a - 2$ is $= d$ the common difference of the arithmetical series, or $d + 2 = a$ the number of angles.

PROB. 1. *To find any Polygonal Number proposed*; having given its side n and angles a. The polygonal number being evidently the sum of the arithmetical progression whose number of terms is n and common difference $a - 2$; and the sum of an arithmetical progression being equal to half the product of the extremes by the number of terms, the extremes being 1 and $1 + d(n - 1) = 1 + (a - 2) \cdot (n - 1)$; therefore that number, or this sum, will be

$\frac{n^2 d - n(d - 2)}{2}$ or $\frac{n^2(a - 2) - n(a - 4)}{2}$, where d is the common difference of the arithmeticals that form the polygonal number, and is always 2 less than the number of angles a.

Hence, for the several kinds of polygons, any particular number whose side is n, will be found from either of these two formulæ, by using for d its values 1, 2, 3, 4, &c; which gives these following formulæ for the polygonal number in each sort, viz, the

Triangular	-	$\frac{1}{2}(n^2 + n)$,
Square	-	$\frac{1}{2}(2n^2 - 0n) = n^2$,
Pentagonal	-	$\frac{1}{2}(3n^2 - n)$,
Hexagonal	-	$\frac{1}{2}(4n^2 - 2n)$,
Heptagonal	-	$\frac{1}{2}(5n^2 - 3n)$,
$m$gonal	-	$\frac{1}{2}[(m - 2)n^2 - (m - 4)n]$.

PROB. 2. *To find Sum of any Number of Polygonal Numbers of any order.*—Let the angles of the polygon be a, or the common difference of the arithmeticals that form the polygonals, d; and n the number of terms in the polygonal series, whose sum is sought: then is

$\frac{1}{6}(n^2 - 1) dn + \frac{1}{2}(n + 1)n$ or $\frac{1}{6}(n^2 - 1) \cdot (a - 2)n + \frac{1}{2}(n + 1)n$

the sum of the n terms sought.

Hence, substituting successively the numbers 1, 2, 3, 4, &c, for d, there is obtained the following particular cases, or formulæ, for the sums of n terms of the several ranks of polygonal numbers, viz, the sum of the

Triangulars	- -	$\frac{1}{6}(n^2 + 3n + 2)n$,
Squares	- -	$\frac{1}{6}(2n^2 + 3n + 1)n$,
Pentagonals	- -	$\frac{1}{6}(3n^2 + 3n + 0)n$,
Hexagonals	- -	$\frac{1}{6}(4n^2 + 3n - 1)n$,
Heptagonals	- -	$\frac{1}{6}(5n^2 + 3n - 2)n$.

&c, which may be illustrated as follows:

And thus may any polygonal number be represented by points in the figure whose name it bears.

Thus, in the above figures, begin with drawing a small polygon that has the number of sides required (as 5 or 6); this number remains constant for one and the same series of polygon numbers, and is always equal to 2 plus the difference of the arithmetical progression from which the series is produced. Then choose one of its angles, in order to draw from the angular point all the diagonals of this polygon, which, with the two sides containing the angle that has been taken, are to be indefinitely produced; after that has been done, take these two sides, and the diagonals of the first polygon on the indefinite lines, each as often as you choose; and draw, from the corresponding points marked by the compasses, lines parallel to the first polygon; and divide them into as many equal parts, or by as many points, as there are actually in the diagonals and the two sides produced.

This rule is general, from the triangle up to the polygon of an infinite number of sides.

Fermat discovered a very curious and general property of polygonal numbers, which is this: That every number is the sum of one, two, or three triangular numbers; the sum of one, two, three, or four squares; the sum of one, two, three, four, or five pentagonal numbers; and so on; that is generally: If m denote any order of polygonal numbers, then any number whatever may be resolved into m polygonal numbers of this order, or a less number.

This curious property has not however been demonstrated, except for the cases of triangles and squares, the other cases seeming to bid defiance to the efforts of those mathematicians who have attempted them. A demonstration for the squares may be seen in Leybourn's Mathematical Repository; and for both the squares and triangles, in Legendre's Essai sur la Theorie des Nombres.

POLYGONOMETRY, the science and principles of polygons. For which, see my Course of Mathematics, last volume.

POLYGRAM, in Geometry, a figure consisting of many lines.

POLYHEDRON, or POLYEDRON, a body or solid contained by many rectilinear planes or sides. When the sides of the polyhedron are regular polygons, all similar and equal, then the polyhedron becomes a regular body, and may be inscribed in a sphere; that is, a sphere may be described about it, so that its surface shall touch all the angles or corners of the solid. There are but five of these regular bodies, viz, the tetraedron, the hexaedron or cube, the octaedron, the dodecaedron, and the icosaedron. See REGULAR *Body*, and each of those five bodies severally.

Gnomonical POLYHEDRON, is a stone with several faces, on which are projected various kinds of dials. Of this sort, that in the Privy-garden, London, now gone to ruin, was esteemed the finest in the world.

POLYHEDRON, in Optics. See POLYSCOPE.

POLYHEDROUS *Figure*, in Geometry, a solid contained under many sides or planes. See POLYHEDRON.

POLYNOMIAL, in Algebra, a quantity of many names or terms, and is otherwise called a Multinomial. As $a + 3b - 2c + 4d$, &c. See MULTINOMIAL.

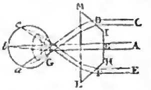
POLYOPTRUM, in Optics, a glass through which objects appear multiplied, but diminished. This differs both in structure and phenomena from the common multiplying glasses called polyhedra or polyscopes.

To construct the Polyoptrum.—From a glass AB, plane on both sides, and about 3 fingers thick, cut out spherical segments, scarce a 5th part of a digit in diameter.—If then the glass be removed to such a distance from the eye, that you can take in all the cavities at one view, you will see the same object, as if through so many several concave glasses as there are cavities, and all exceeding small.—Fit this, as an object-glass, in a tube ABCD, whose aperture AB is equal to the diameter of the glass, and the other CD is equal to that of an eye-glass, as for instance about a finger's breadth. The length of the tube AC is to be accommodated to the object-glass and eye-glass, by trial. In CD fit a convex eye-glass, or in its stead a meniscus having the distance of its principal focus a little larger than

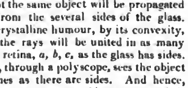
the length of the tube; so that the point from which the rays diverge after refraction in the object-glass, may be in the focus. If then the eye be applied near the eye-glass, a single object will be seen repeated as often as there are cavities in the object-glass, but still diminished.

POLYSCOPE, or POLYHEDRON, in Optics, is a multiplying glass, being a glass or lens which represents a single object to the eye as if it were many. It consists of several plane surfaces, disposed into a convex form, through every one of which the object is seen.

Phenomena of the Polyscope.—1. If several rays, as EF, AB, CD, fall parallel on the surface of a polyscope, they will continue parallel after refraction. If then the polyscope be supposed regular, LH, HI, IM will be as tangents cutting the spherical convex lens in F, B, and D; and consequently, rays falling on the points of contact, intersect the axis. Therefore, since the rest are parallel to these, they will also mutually intersect each other in G.—Hence, if the eye be placed where parallel rays decussate, rays of the same object will be propagated to it still parallel from the several sides of the glass. Therefore, since the crystalline humour, by its convexity, unites parallel rays, the rays will be united in as many different points of the retina, *a*, *b*, *c*, as the glass has sides. Consequently the eye, through a polyscope, sees the object repeated as many times as there are sides. And hence, since rays coming from very remote objects are parallel, a remote object is seen through a polyscope as often repeated as that has sides.



2. If rays AB, AC, AD, coming from a radiant point A, fall on several sides of a regular polyscope; after refraction they will decussate in G, and proceed on a little diverging.—Hence, if the eye be placed where the rays decussate after coming from the several planes, the rays will be propagated to it from the several planes a little diverging, or as if they proceeded from different points. But since the crystalline humour, by its convexity, collects rays from several points into the same point; the rays will be united in as many different points of the retina, *a*, *b*, *c*, as the glass has sides; and consequently the eye, being placed in the focus G, will see even a near object through the polyscope as often repeated as that has sides.



Thus may the images of objects be multiplied in a camera obscura, by placing a polyscope at its aperture, and adding a convex lens at a due distance from it. And it makes a very pleasant appearance, if a prism be applied so that the coloured rays of the sun refracted from it be received on the polyscope: for by this means they will be thrown on a paper or wall near at hand in little lucid specks, much exceeding the brightness of any precious stone; and in the focus of the polyscope, where the rays decussate (for in this experiment they are received on the convex side), will be a star of surprising lustre.

Farther, if images be painted in water-colours in the areolæ or little squares of a polyscope, and the glass be applied to the aperture of a camera obscura; the sun's rays, passing through it, will carry with them the images, and project them on the opposite wall.—This artifice bears a resemblance to that other, by which an image on paper is projected on the camera; viz, by wetting the paper with oil, and straining it tight in a frame; then applying it to the aperture of the camera obscura, so that the rays of a candle may pass through it upon the polyscope.

To make an Anamorphosis, or Deformed Image, which shall appear regular and beautiful through a Polyscope, or Multiplying Glass.—At one end of a horizontal table erect another perpendicularly, on which a figure may be designed; and on the other end erect another, to serve as a fulcrum or support, moveable on the horizontal one. To the fulcrum apply a plano-convex polyscope, consisting, for example, of 24 plane triangles; and let the polyscope be fitted in a draw-tube, of which that end towards the eye may have only a very small aperture, and a little farther off than the focus. Remove the fulcrum from the other perpendicular table, till it be out of the distance of the focus; and the more so, as the image is to be greater. Before the little aperture place a lamp; and trace the luminous areolæ projected from the sides of the polyscope, with a black lead pencil, on the vertical plane, or a paper applied upon it.

In the several areolæ, design the different parts of an image, in such a manner as that, when joined together, they may make one whole, looking every now and then through the tube to guide and correct the colours, and to see that the several parts match and fit well together. As to the intermediate space, it may be filled up with any figures or designs at pleasure, contriving it so, as that to the naked eye the whole may exhibit some appearance very different from that intended to appear through the polyscope.—The eye, now looking through the small aperture of the tube, will see the several parts and members dispersed among the areolæ to exhibit one continued image, all the intermediate parts disappearing. See ANAMORPHOSIS.

POLYSPASTON, in Mechanics, a machine so called by Vitruvius, consisting of an assemblage of several pulleys, used for raising heavy weights.

PONTON, or PONTOON, a kind of flat-bottomed boat, whose carcase of wood is lined within and without with tin. Some nations line them on the outside only, and that with plates of copper, which is better. Our pontoons are 21 feet long, nearly 5 feet broad, and 2 feet 1¼ inch deep within. They are carried along with an army upon carriages, to make temporary bridges, called pontoon-bridges.

PONTOON-*Bridge*, a bridge made of pontoons slipped into the water, and moored by anchors and otherwise fastened together by ropes, at small distances from one another; then covered by beams of timber passing over them; upon which is laid a flooring of boards. By this means, whole armies of infantry, cavalry, and artillery are quickly passed over rivers.—For want of pontoons, &c, bridges are sometimes formed of empty powder-casks, or powder-barrels, which support the beams and flooring. Julius Cæsar and Aulus Gellius both mention pontoons (pontones); but theirs were no more than a kind of square flat vessels, proper for carrying over horse, &c.

PONT-VOLANT, or *Flying-bridge*, is a kind of bridge used in sieges, for surprising a post or outwork that has but narrow moats. It is made of two small bridges laid over each other, and so contrived that, by means of cords and pulleys placed along the sides of the under bridge, the upper may be pushed forwards, till it join the place where it is designed to be fixed. The whole length of both ought not to be above 5 fathoms, lest it should break with the weight of the men.

POPULATION *of the World*.—From Le Sage's Atlas, 1814, is in

	Millions.
Europe - - -	170
Asia . - -	380
Africa - - -	90
America, North - -	30
——— South - -	20

Total population of the globe -	710

PORCH, in Architecture, a kind of vestibule supported by columns; much used at the entrance of the ancient temples, halls, churches, &c. Such is that before the door of St. Paul's, Covent Garden.

When a porch had four columns in front, it was called a tetrastyle; when six, hexastyle; when eight, octostyle, &c. See *Tetrastyle*, &c.

PORES, are the small interstices between the particles of matter which compose bodies; and are either empty, or filled with some insensible medium.—Condensation and rarefaction are only performed by closing and opening the pores. Also the transparency of bodies is supposed to arise from their pores being directly opposite to one another. And the matter of insensible perspiration is conveyed through the pores of the cutis.—Mr. Boyle has a particular essay on the porosity of bodies, in which he proves that the most solid bodies have some kind of pores: and indeed if they had not, all bodies would be alike specifically heavy.

Sir Isaac Newton shows, that bodies are much more rare and porous than is commonly believed. Water, for example, is 19 times lighter and rarer than gold; and gold itself is so rare, as very readily, and without the least opposition, to transmit magnetic effluvia, and easily to admit even quicksilver into its pores, and to let water pass through it: for a concave sphere of gold hath, when filled with water, and soldered up, upon pressing it with a great force, suffered the water to squeeze through it, and stand all over its outside, in multitudes of small drops like dew, without bursting or cracking the gold. Whence it may be concluded, that gold has more pores than solid parts, and consequently that water has above 40 times more pores than parts. Hence it is that the magnetic effluvia passes freely through all cold bodies that are not magnetic; and that the rays of light pass, in right lines, to the greatest distances through pellucid bodies.

PORIME, *Porima*, in Geometry, a kind of easy lemma, or theorem so easily demonstrated, that it is almost self-evident: such, for example, as that a chord is wholly within the circle.—Porime stands opposed to aporime, which denotes a proposition so difficult, as to be almost impossible to be demonstrated, or effected. Such as the quadrature of the circle, &c.

PORISM, *Porisma*, in Geometry, has by some been defined a general theorem, or canon, deduced from a geometrical locus, and serving for the solution of other general and difficult problems. Proclus derives the word from the Greek πορίζω, *I establish*, and conclude from something already done and demonstrated: and accordingly he defines porisma a theorem drawn occasionally from some other theorem already proved: in which sense it agrees with what is otherwise called corollary, and was much used as such even by the geometers two or three centuries ago.

Pappus says, A porism is that in which something was proposed to be investigated, or something between a theorem and a problem. Others derive it from πόρος, *a passage*, and make it of the nature of a lemma, or a proposition necessary for passing to another more important one.

But Dr. Simson, rejecting the accounts that have been given of a porism, defines it a proposition, either in the form of a problem or a theorem, in which it is proposed either to investigate, or demonstrate. And Mr. Playfair says, A porism is nothing else than that particular case, when the data of a problem are so related to one another as to render it indefinite, or capable of innumerable solutions. Edinburgh Philos. Trans. vol. 1, pa. 60.

Euclid wrote three books of porisms, being a curious collection of various things relating to the analysis of the more difficult and general problems. Those books however are lost; and nothing remains in the works of the ancient geometricians concerning this subject, besides what Pappus has preserved, in a very imperfect and obscure state, in his Mathematical Collections, viz, in the introduction to the 7th book.

Several attempts have been made to restore these writings in some degree, besides that which Pappus has left upon the subject. Thus, Fermat has given a few propositions of this kind; which are to be found in the collection of his works, in folio, 1679, pa. 116. The like was done by Bulliald, in his Exercitationes Geometricæ, 4to, 1657. Dr. Robert Simson gave also a specimen, in two propositions, in the Philos. Trans. vol. 32, pa. 330; and besides left behind him a considerable treatise on the subject of porisms, which has been printed in an edition of his works, at the expense of the earl of Stanhope, in 4to, 1776; an English translation of a part of which was published by Mr. Lawson in the year following.

The whole three books of Euclid were also restored by that ingenious mathematician Albert Girard, as appears by two notices that he gave, first in his Trigonometry, printed in French, at the Hague, in 1629, and also in his edition of the works of Stevinus, printed at Leyden in 1634, pa. 459; but whether his intention of publishing them was ever carried into execution, I have not been able to learn.

A learned paper on the subject of porisms, by the very ingenious professor Playfair, was inserted in the 3d volume of the Transactions of the Royal Society of Edinburgh. And as this paper contains a number of curious observations on the geometry of the ancients in general, as well as forms a complete treatise as it were on porism in particular, a pretty considerable abstract of it cannot but be deemed in this place very useful and important.

"The restoration of the ancient books of geometry (says the learned professor) would have been impossible, without the coincidence of two circumstances, of which, though the one is purely accidental, the other is essentially connected with the nature of the mathematical sciences. The first of these circumstances is the preservation of a short abstract of those books, drawn up by Pappus Alexandrinus, together with a series of such lemmata, as he judged useful to facilitate the study of them. The second is, the necessary connection that takes place among the objects of every mathematical work, which, by excluding whatever is arbitrary, makes it possible to determine the whole course of an investigation, when only a few points in it are known. From the union of these circumstances, mathematics has enjoyed an advantage of which no other branch of knowledge can partake; and while the critic or the historian has only been able to lament the fate of those books of Livy and Tacitus which are lost, the geometer has had the high satisfaction to behold the works of Euclid and Apollonius reviving under his hands.

"The first restorers of the ancient books were not, however, aware of the full extent of the work which they had undertaken. They thought it sufficient to demonstrate the propositions, which they knew from Pappus, to have been contained in those books; but they did not follow the ancient method of investigation, and few of them appear to have had any idea of the elegant and simple analysis by which these propositions were originally discovered, and by which the Greek geometry was peculiarly distinguished.

"Among these few, Fermat and Halley are to be particularly remarked. The former, one of the greatest mathematicians of the last age, and a man in all respects of superior abilities, had very just notions of the geometrical analysis, and appears often abundantly skilful in the use of it; yet in his restoration of the Loci Plani, it is remarkable, that in the most difficult propositions, he lays aside the analytical method, and contents himself with giving the synthetical demonstration. The latter, among the great number and variety of his literary occupations, found time for a most attentive study of the ancient mathematicians, and was an instance of, what experience shows to be much rarer than might be expected, a man equally well acquainted with the ancient and the modern geometry, and equally disposed to do justice to the merit of both. He restored the books of Apollonius, on the problem De Sectione Spatii, according to the true principles of the ancient analysis.

"These books however are but short, so that the first restoration of considerable extent that can be reckoned complete, is that of the Loci Plani by Dr. Simson, published in 1749; which, if it differs at all from the work it is intended to replace, seems to do so only by its greater excellence. This much at least is certain, that the method of the ancient geometers does not appear to greater advantage in the most entire of their writings, than in the restoration above mentioned: and that Dr. Simson has often sacrificed the elegance to which his own analysis would have led, in order to tread more exactly in what the lemmata of Pappus pointed out to him, as the track which Apollonius had pursued.

"There was another subject, that of porisms, the most intricate and enigmatical of any thing in the ancient geometry, which was still reserved to exercise the genius of Dr. Simson, and to call forth that enthusiastic admiration of antiquity, and that unwearied perseverance in research, for which he was so peculiarly distinguished. A treatise in three books, which Euclid had composed on porisms, was lost, and all that remained concerning them was an abstract of that treatise, inserted by Pappus Alexandrinus in his Mathematical Collections, in which, had it been entire, the geometers of later times would doubtless have found wherewithal to console themselves for the loss of the original work. But unfortunately it has suffered so much from the injuries of time, that all which we can immediately learn from it is, that the ancients put a high value on the propositions which they called porisms, and regarded them as a very important part of their analysis. The porisms of Euclid are said to be, "Collectio artificiosissima multarum rerum quæ spectant ad analysin difficiliorum et generalium problematum." The curiosity, however, which is excited by this encomium is quickly disappointed; for when Pappus proceeds to explain what a porism is, he lays down two definitions of it, one of which is rejected by him as imperfect, while the other, which is stated as correct, is too vague and indefinite to convey any useful information.

"These defects might nevertheless have been supplied, if the enumeration which he next gives of Euclid's Propositions had been entire; but on account of the extreme brevity of his enunciations, and their reference to a diagram which is lost, and for the constructing of which no directions are given, they are all, except one, perfectly unintelligible. For these reasons, the fragment in question is so obscure, that even to the learning and penetration of Dr. Halley it seemed impossible that it could ever be explained; and he therefore concluded, after giving the Greek text with all possible correctness, and adding the Latin translation, 'Hactenus Porismatum descriptio nec mihi intellecta, nec lectori profutura. Neque aliter fieri potuit, tam ob defectum schematis cujus fit mentio, quam ob omissa quædam et transposita, vel aliter vitiata in propositionis generalis expositione, unde quid sibi velit Pappus haud mihi datum est conjicere. His adde dictionis modum nimis contractum, ac in re difficili, qualis hæc est, minime usurpandum.'

"It is true, however, that before this time, Fermat had attempted to explain the nature of porisms, and not altogether without success. Guiding his conjectures by the definition which Pappus censures as imperfect, because it defined porisms only 'ab accidente,' viz, 'porisma est quod deficit hypothesi a Theoremate Locali,' he formed to himself a tolerably just notion of these propositions, and illustrated his general description by examples that are in effect porisms. But he was able to proceed no farther; and he neither proved, that his notion of a porism was the same with Euclid's, nor attempted to restore, or explain any one of Euclid's propositions; much less did he suppose, that they were to be investigated by an analysis peculiar to themselves. And so imperfect indeed was this attempt, that the complete restoration of the porisms was necessary to prove, that Fermat had even approximated to the truth.

"All this did not however deter Dr. Simson from turning his thoughts to the same subject, which he appears to have done very early, and long before the publication of the Loci Plani in 1749.

"The account he gives of his progress, and of the obstacles he encountered, will be always interesting to mathematicians. 'Postquam vero apud Pappum legeram; porismata Euclidis collectionem fuisse artificiosissimam multarum rerum, quæ spectant ad analysin difficiliorum et generalium problematum, magno desiderio tenebar, aliquid de iis cognoscendi; quare sæpius et multis variisque viis tum Pappi propositionem generalem, mancam et imperfectam, tum primum lib. i.

"'Porisma, quod solum ex omnibus in tribus libris integrum adhuc manet, intelligere et restituere conabar; frustra tamen, nihil enim proficiebam. Cumque cogitationes de hac re multum mihi temporis consumpserint, atque molestæ admodum evaserint, firmiter animum induxi hæc nunquam in posterum investigare; præsertim cum optimus geometra Halleius spem omnem de iis intelligendis abjecisset. Unde quoties menti occurrebant, toties eas arcebam. Postea tamen accidit, ut improvidum et propositi immemorem invaserint, meque detinuerint donec tandem lux quædam effulserit, quæ spem mihi faciebat inveniendi saltem Pappi propositionem generalem, quam quidem multa investigatione tandem restitui. Hæc autem paulo post una cum Porismate primo lib. i. impressa est inter Transactiones Phil. anni 1723, num. 177.'

"The propositions mentioned, as inserted in the Philosophical Transactions for 1723, are all that Dr. Simson published on the subject of porisms during his life, though he continued his investigations concerning them, and succeeded in restoring a great number of Euclid's propositions, together with their analysis. The propositions thus restored form a part of that valuable edition of the posthumous works of this geometer which the mathematical world owes to the munificence of the late earl Stanhope.

"The subject of porisms is not however exhausted, nor is it yet placed in so clear a light as to need no further illustration. It yet remains to enquire into the probable origin of these propositions, that is to say, into the steps by which the ancient geometers appear to have been led to the discovery of them.

"It remains also to point out the relations in which they stand to the other classes of geometrical truths; to consider the species of analysis, whether geometrical or algebraical, that belongs to them: and, if possible, to assign the reason why they have so long escaped the notice of modern mathematicans. It is to these points that the following observations are chiefly directed.

"I begin with describing the steps that appear to have led the ancient geometers to the discovery of porisms; and must here supply the want of express testimony by probable reasonings, such as are necessary, whenever we would trace remote discoveries to their sources, and which have more weight in mathematics than in any other of the sciences.

"It cannot be doubted, that it has been the solution of problems, which, in all states of the mathematical sciences, has led to the discovery of most geometrical truths. The first mathematical enquiries, in particular, must have occurred in the form of questions, where something was given, and something required to be done; and by the reasonings necessary to answer these questions, or to discover the relation between the things that were given and those that were to be found, many truths were suggested, which came afterwards to be the subjects of separate demonstration. The number of these was the greater, as the ancient geometers always undertook the solution of problems with a scrupulous and minute attention, which would scarcely suffer any of the collateral truths to escape their observation. We know from the examples which they have left us, that they never considered a problem as resolved, till they had distinguished all its varieties, and evolved separately every different case that could occur, carefully remarking whatever change might arise in the construction, from any change that was supposed to take place among the magnitudes which were given.

"Now as this cautious method of proceeding was not better calculated to avoid error, than to lay hold of every truth that was connected with the main object of enquiry, these geometers soon observed, that there were many problems which, in certain circumstances, would admit of no solution whatever, and that the general construction by which they were resolved would fail, in consequence of a particular relation being supposed among the quantities which were given.

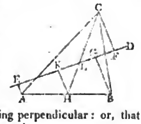
"Such problems were then said to become impossible; and it was readily perceived, that this always happened, when one of the conditions prescribed was inconsistent with the rest, so that the supposition of their being united in the same subject, involved a contradiction. Thus, when it was required to divide a given line, so that the rectangle under its segments should be equal to a given space, it was evident, that if this space was greater than the square of half the given line, the thing required could not possibly be done; the two conditions, the one defining the magnitude of the line, and the other that of the rectangle under its segments, being then inconsistent with one another. Hence an infinity of beautiful propositions concerning the maxima and the minima of quantities, or the limits of the possible relations which quantities may stand in to one another.

"Such cases as these would occur even in the solution of the simplest problems; but when geometers proceeded to the analysis of such as were more complicated, they must have remarked, that their constructions would sometimes fail, for a reason directly contrary to that which has now been assigned. Instances would be found where the lines that, by their intersection, were to determine the thing sought, instead of intersecting one another, as they did in general, or of not meeting at all, as in the above-mentioned case of impossibility, would coincide with one another entirely, and leave the question of consequence unresolved. But though this circumstance must have created considerable embarrassment to the geometers who first observed it, as being perhaps the only instance in which the language of their own science had yet appeared to them ambiguous or obscure, it would not probably be long till they found out the true interpretation to be put on it. After a little reflection, they would conclude, that since, in the general problem, the magnitude required was determined by the intersection of the two lines above mentioned, that is to say, by the points common to them both; so, in the case of their coincidence, as all their points were in common, every one of these points must afford a solution; which solutions therefore must be infinite in number; and also, though infinite in number, they must all be related to one another, and to the things given, by certain laws, which the position of the two coinciding lines must necessarily determine.

"On enquiring farther into the peculiarity in the state of the data which had produced this unexpected result, it might likewise be remarked, that the whole proceeded from one of the conditions of the problem involving another, or necessarily including it; so that they both together made in fact but one, and did not leave a sufficient number of independent conditions, to confine the problem to a single solution, or to any determinate number of solutions. It was not difficult afterwards to perceive, that these cases of problems formed very curious propositions, of an intermediate nature between problems and theorems, and that they admitted of being enunciated separately, in a manner peculiarly elegant and concise. It was to such propositions, so enunciated, that the ancient geometers gave the name of porisms.

"This deduction requires to be illustrated by examples." Mr. Playfair then gives several problems by way of illustration; one of which, which may here suffice to show the method, is as follows:

"A triangle ABC being given, and also a point D; to draw through D a straight line DG, such, that, perpendiculars being drawn to it from the three angles of the triangle, viz, AE, BG, CF, the sum of the two perpendiculars on the same side of DG, shall be equal to the remaining perpendicular: or, that AE and BG together, may be equal to CF.



"Suppose it done: Bisect AB in H, join CH, and draw HK perpendicular to DG.—Because AB is bisected in H, the two perpendiculars AE and BG are together double of HK; and as they are also equal to CF by hypothesis, CF must be double of HK; and CL of LH. Now, CH is given in position, and magnitude; therefore the point L is given; and the point D being also given, the line DL is given in position, which was to be found.

"The construction was obvious. Bisect AB in H, join CH, and take HL equal to one third of CH; the straight line which joins the points D and L is the line required.

"Now, it is plain, that while the triangle ABC remains the same, the point L also remains the same, wherever the point D may be. The point D may therefore coincide with L; and when this happens, the position of the line to be drawn is left undetermined; that is to say, any line whatever drawn through L will satisfy the conditions of the problem. Here therefore we have another indefinite case of a problem, and of consequence another porism, which may be thus enunciated: "A triangle being given in position, a point in it may be found, such, that any straight line whatever being drawn through that point, the perpendiculars drawn to this straight line from the two angles of the triangle which are on one side of it, will be together equal to the perpendicular that is drawn to the same line from the angle on the other side of it.

"This porism may be made much more general; for if, instead of the angles of a triangle, we suppose ever so many points to be given in a plane, a point may be found such, that any straight line being drawn through it, the sum of all the perpendiculars that fall on that line from the given points on one side of it, is equal to the sum of the perpendiculars that fall on it from all the points on the other side of it.

"Or still more generally, any number of points being given not in the same plane, a point may be found, through which if any plane be supposed to pass, the sum of all the perpendiculars which fall on that plane from the points on one side of it, is equal to the sum of all the perpendiculars that fall on the same plane from the points on the other side of it. It is unnecessary to observe, that the point to be found in these propositions, is no other than the centre of gravity of the given points; and that therefore we have here an example of a porism very well known to the modern geometers, though not distinguished by them from other theorems."

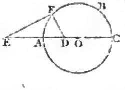
After some examples of other porisms, and remarks upon them, the author then adds,

"From this account of the origin of porisms, it follows, that a porism may be defined, *A proposition affirming the possibility of finding such conditions as will render a certain problem indeterminate, or capable of innumerable solutions.*

"To this definition, the different characters which Pappus has given will apply without difficulty. The propositions described in it, like those which he mentions, are, strictly speaking, neither theorems nor problems, but of an intermediate nature between both; for they neither simply enunciate a truth to be demonstrated, nor propose a question to be solved, but are affirmations of a truth, in which the determination of an unknown quantity is involved. In as far therefore as they assert, that a certain problem may become indeterminate, they are of the nature of theorems; and in as far as they seek to discover the conditions by which that is brought about, they are of the nature of problems.

"In the preceding definition also, and the instances from which it is deduced, we may trace that imperfect description of porisms which Pappus ascribes to the later geometers, viz, 'Porisma est quod deficit hypothesi a theoremate locali.' Now, to understand this, it must be observed, that if we take the converse of one of the propositions called Loci, and make the construction of the figure a part of the hypothesis, we have what was called by the ancients a Local Theorem. And again, if, in enunciating this theorem, that part of the hypothesis which contains the construction be suppressed, the proposition arising from thence will be a porism; for it will enunciate a truth, and will also require, to the full understanding and investigation of that truth, that something should be found, viz, the circumstance in the construction, supposed to be omitted.

"Thus when we say; If from two given points E and D, two lines EF and FD are inflected to a third point F, so as to be to one another in a given ratio, the point F is in the circumference of a circle given in position: we have a Locus.



"But when conversely it is said; If a circle ABC, of which the centre is O, be given in position, as also a point E, and if D be taken in the line EO, so that the rectangle EO, OD be equal to the square of AO, the semidiameter of the circle; and if from E and D, the lines EF and DF be inflected to any point whatever in the circumference ABC; the ratio of EF to DF will be a given ratio, and the same with that of EA to AD: we have a local theorem.

"And, lastly, when it is said; If a circle ABC be given in position, and also a point E, a point D may be found, such, that if the two lines EF and FD be inflected from E and D, to any point whatever F, in the circumference, these lines shall have a given ratio to one another: the proposition becomes a porism.

"Here it is evident, that the local theorem is changed into a porism, by leaving out what relates to the determination of the point D, and of the given ratio. But though all propositions formed in this way, from the conversion of Loci, be porisms, yet all porisms are not formed from the conversion of Loci. The first and second of the preceding, for instance, cannot by conversion be changed into Loci; and therefore the definition which describes all porisms as being so convertible, is not sufficiently comprehensive. Fermat's idea of porisms, as has been already observed, was founded wholly on this definition, and therefore could not fail to be imperfect.

"It appears therefore, that the definition of porisms given above, agrees with Pappus's idea of these propositions, as far at least as can be collected from the imperfect fragments which contain his general description of them. It agrees also with Dr. Simson's definition, which is this: 'Porisma est propositio in qua proponitur demonstrare rem aliquam, vel plures datas esse, cui, vel quibus, ut et cuilibet ex rebus innumeris, non quidem datis, sed quæ ad ea quæ data sunt eandem habent relationem, convenire ostendendum est affectionem quandam communem in propositione descriptam.'

"It cannot be denied, that there is a considerable degree of obscurity in this definition; notwithstanding which it is certain, that every proposition to which it applies must contain a problematical part, viz, 'in qua proponitur demonstrare rem aliquam, vel plures datas esse,' and also a theoretical part, which contains the property, or communis affectio, affirmed of certain things which have been previously described.

"It is also evident, that the subject of every such proposition, is the relation between magnitudes of three different kinds; determinate magnitudes which are given; determinate magnitudes which are to be found; and indeterminate magnitudes which, though unlimited in number, are connected with the others by some common property. Now, these are exactly the conditions contained in the definitions that have been given here.

"To confirm the truth of this theory of the origin of porisms, or at least the justness of the notions founded on it, I must add a quotation from an essay on the same subject, by a member of this society, the extent and correctness of whose views make every coincidence with his opinions peculiarly flattering. In a paper read several years ago before the Philosophical Society, Professor Dugald Stewart defined a porism to be 'A proposition affirming the possibility of finding one or more of the conditions of an indeterminate theorem.' Where, by an indeterminate theorem, as he had previously explained it, is meant one which expresses a relation between certain quantities that are indeterminate, both in magnitude and in number. The near agreement of this with the definition and explanations which have been given above, is too obvious to require to be pointed out; and I have only to observe, that it was not long after the publication of Simson's posthumous works, when, being both of us occupied in speculations concerning porisms, we were led separately to the conclusions which I have now stated.

"In an enquiry into the origin of porisms, the etymology of the term ought not to be forgotten. The question indeed is not about the derivation of the word Πορισμα, for concerning that there is no doubt; but about the reason why this term was applied to the class of propositions above described. Two opinions may be formed on this subject, and each of them with considerable probability; 1mo. One of the significations of ποριζω, is *to acquire* or *obtain*; and hence Πορισμα, the *thing obtained* or *gained*.

"Accordingly, Scapula says, 'Est vox a geometris desumpta qui theorema aliquid ex demonstrativo syllogismo necessario sequens inferentes, illud quasi lucrari dicuntur, quod non ex professo quidem theorematis hujus instituta sit demonstratio, sed tamen ex demonstratis recte sequatur.' In this sense Euclid uses the word in his Elements of Geometry, where he calls the corollaries of his proposition, porismata. This circumstance creates a presumption, that when the word was applied to a particular class of propositions, it was meant, in both cases, to convey nearly the same idea; as it is not at all probable, that so correct a writer as Euclid, and so scrupulous in his use of words, should employ the same term to express two ideas which are perfectly different. May we not therefore conjecture, that these propositions got the name of porisms, entirely with a reference to their origin? According to the idea explained above, they would in general occur to mathematicians when engaged in the solution of the more difficult problems, and would arise from those particular cases, where one of the conditions of the data involved in it some one of the rest. Thus a particular kind of theorem would be obtained, following as a corollary from the solution of the problem: and to this theorem the term Πορισμα might be very properly applied, since, in the words of Scapula, already quoted, 'Non ex professo theorematis hujus instituta sit demonstratio, sed tamen ex demonstratis recte sequatur.'

"2do. But though this interpretation agrees so well with the supposed origin of porisms, it is not free from difficulty. The verb ποριζω has another signification, *to find out, to discover, to devise*; and is used in this sense by Pappus, when he says that the propositions called porisms, afford great delight, τοις δυναμενοις ορᾳν και πορίζειν, *to those who are able to understand and investigate.* Hence comes πορισμος, the *act of finding out* or *discovering*, and from πορισμος, in this sense, the same author evidently considers Πορισμα as being derived. His words are, Εφασαν δε (οἱ αρχαιοι) Πορισμα ειναι το προτεινομενον εις Πορισμον αυτετε προτεινομενε, *The ancients said, that a Porism is something proposed for the* finding out, or discovering *of the very thing proposed.* It seems singular, however, that porisms should have taken their name from a circumstance common to them with so many other geometrical truths; and if this was really the case, it must have been on account of the enigmatical form of their enunciations, which required, that in the analysis of these propositions, a sort of double discovery should be made, not only of the truth, but also of the meaning of the very thing which was proposed. They may therefore have been called porismata, or investigations, by way of eminence.

"We might next proceed to consider the particular porisms which Dr. Simson has restored, and to show, that every one of them is the indeterminate case of some problem. But of this it is so easy for any one, who has attended to the preceding remarks, to satisfy himself, by barely examining the enunciations of those propositions, that the detail, unto which it would lead, seems to be unnecessary. I shall therefore go on to make some observations on that kind of analysis which is particularly adapted to the investigation of porisms.

"If the idea which we have given of these propositions be just, it follows, that they are always to be discovered by considering the cases in which the construction of a problem fails in consequence of the lines which, by their intersection, or the points which, by their position, were to determine the magnitude required, happening to coincide with one another—a porism may therefore be deduced from the problem it belongs to, in the same manner that the propositions concerning the maxima and minima of quantities are deduced from the problems of which they form the limitations; and such no doubt is the most natural and most obvious analysis of which this class of propositions will admit.

"It is not, however, the only one that they will admit of; and there are good reasons for wishing to be provided with another, by means of which, a porism that is any how suspected to exist, may be found out, independently of the general solution of the problem to which it belongs. Of these reasons, one is, that the porism may perhaps admit of being investigated more easily than the general problem admits of being resolved; and another is, that the former, in almost every case, helps to discover the simplest and most elegant solution that can be given of the latter.

"It is desirable to have a method of investigating porisms, which does not require that we should previously resolve the problems they are connected with, and which may always serve to determine, whether to any given problem there be attached a porism, or not. Dr. Simson's Analysis may be considered as answering to this description; for as that geometer did not regard these propositions at all in the light that is done here, nor in relation to their origin, an independent analysis of this kind was the only one that could occur to him; and he has accordingly given one which is extremely ingenious, and by no means easy to be invented, but which he uses with great skilfulness and dexterity throughout the whole of his Restoration.

"It is not easy to ascertain whether this be the precise method used by the ancients. Dr. Simson had here nothing to direct him but his genius, and has the full merit of the first inventor. It seems probable, however, that there is at least a great affinity between the methods, since the lemmata given by Pappus as necessary to Euclid's demonstrations, are subservient also to those of our modern geometer.

"It is, as we have seen, a general principle, that a problem is converted into a porism, when one, or when two, of the conditions of it, necessarily involve in them some one of the rest. Suppose then that two of the conditions are exactly in that state which determines the third; then, while they remain fixed or given, should that third one be supposed to vary, or differ, ever so little, from the state required by the other two, a contradiction will ensue. Therefore if, in the hypothesis of a problem, the conditions be so related to one another, as to render it indeterminate, a porism is produced; but if, of the conditions thus related to one another, some one be supposed to vary, while the others continue the same, an absurdity follows, and the problem becomes impossible. Wherever therefore any problem admits both of an indeterminate, and an impossible case, it is certain, that these cases are nearly related to one another, and that some of the conditions by which they are produced, are common to both.

"It is supposed above, that two of the conditions of a problem involve in them a third; and wherever that happens, the conclusion which has been deduced will invariably take place.

"But a porism may sometimes be so simple, as to arise from the mere coincidence of one condition of a problem with another, though in no case whatever, any inconsistency can take place between them. Thus, in the second of the foregoing propositions, the coincidence of the point given in the problem with another point, viz. the centre of gravity of the given triangle, renders the problem indeterminate; but as there is no relation of distance, or position, between these points, that may not exist, so the problem has no impossible case belonging to it. There are, however, comparatively but few porisms so simple in their origin as this, or that arise from problems in which the conditions are so little complicated; for it usually happens, that a problem which can become indefinite, may also become impossible; and if so, the connection between these cases, which has been already explained, never fails to take place.

"Another species of impossibility may frequently arise from the porismatic case of a problem, which will very much affect the application of geometry to astronomy, or any of the sciences of experiment or observation. For when a problem is to be resolved by help of data furnished by experiment or observation, the first thing to be considered is, whether the data so obtained, be sufficient for determining the thing sought; and in this a very erroneous judgment may be formed, if we rest satisfied with a general view of the subject. For though the problem may in general be resolved from the data that we are provided with, yet these data may be so related to one another in the case before us, that the problem will become indeterminate, and instead of one solution, will admit of an infinite number.

"Suppose, for instance, that it were required to determine the position of a point F from knowing that it was situated in the circumference of a given circle ABC, and also from knowing the ratio of its distances from two given points E and D; it is certain that in general these data would be sufficient for determining the situation of F. But nevertheless, if E and D should be so situated, that they were in the same straight line with the centre of the given circle; and if the rectangle under their distances from that centre, were also equal to the square of the radius of the circle, then, the position of F could not be determined.

"This particular instance may not indeed occur in any of the practical applications of geometry; but there is one of the same kind which has actually occurred in astronomy. And as the history of it is not a little singular, affording besides an excellent illustration of the nature of porisms, I hope to be excused for entering into the following detail concerning it.

"Sir Isaac Newton having demonstrated, that the trajectory of a comet is a parabola, reduced the actual determination of the orbit of any particular comet to the solution of a geometrical problem, depending on the properties of the parabola, but of such considerable difficulty, that it is necessary to take the assistance of a more elementary problem, in order to find, at least nearly, the distance of the comet from the earth, at the times when it was observed. The expedient for this purpose, suggested by Newton himself, was to consider a small part of the comet's path as rectilineal, and described with an uniform motion, so that four observations of the comet being made at moderate intervals of time from one another, four straight lines would be determined, viz. the four lines joining the places of the earth and the comet, at the times of observation, across which if a straight line were drawn, so as to be cut by them in three parts, in the same ratios with the intervals of time above-mentioned; the line so drawn would nearly represent the comet's path, and by its intersection with the given lines, would determine, at least nearly, the distances of the comet from the earth at the time of observation.

"The geometrical problem here employed, of drawing a line to be divided by four other lines given in position, into parts having given ratios to one another, had been already resolved by Dr. Wallis and Sir Christopher Wren, and to their solutions Sir Isaac Newton added three others of his own, in different parts of his works. Yet none of all these geometers observed that peculiarity in the problem which rendered it inapplicable to astronomy. This was first done by M. Boscovich, but not till after many trials, when, on its application to the motion of comets, it had never led to any satisfactory result. The errors it produced in some instances were so considerable, that Zanotti, seeking to determine by it the orbit of the comet of 1739, found, that his construction threw the comet on the side of the sun opposite to that on which he had actually observed it. This gave occasion to Boscovich, some years afterwards, to examine the different cases of the problem, and to remark that, in one of them, it became indeterminate, and that, by a curious coincidence, this happened in the only case which could be supposed applicable to the astronomical problem above-mentioned; in other words, he found, that in the state of the data, which must there always take place, innumerable lines might be drawn, that would be all cut in the same ratio, by the four lines given in position. This be demonstrated in a dissertation published at Rome in 1749, and since that time in the third volume of his Opuscula. A demonstration of it, by the same author, is also inserted at the end of Castillon's Commentary on the Arithmetica Universalis, where it is deduced from a construction of the general problem, given by Mr. Thomas Simpson, at the end of his Elements of Geometry. The proposition, in Boscovich's words, is this: 'Problema quo quæritur recta linea quæ quatuor rectas positione datas ita secet, ut tria ejus segmenta sint invicem in ratione data, evadit aliquando indeterminatum, ita ut per quodvis punctum cujusvis ex iis quatuor rectis duci possit recta linea, quæ ei conditioni faciat satis.'

" It is needless, I believe, to remark, that the proposition thus enunciated is a porism, and that it was discovered by Boscovich, in the same way in which I have supposed porisms to have been first discovered by the geometers of antiquity.

" A question nearly connected with the origin of porisms still remains to be solved, namely, from what cause has it arisen that propositions which are in themselves so important, and that actually occupied so considerable a place in the ancient geometry, have been so little remarked in the modern? It cannot indeed be said, that propositions of this kind were wholly unknown to the moderns before the restoration of what Euclid had written concerning them; for besides Boscovich's proposition, of which so much has been already said, the theorem which asserts, that in every system of points there is a centre of gravity, has been shown above to be a porism; and we shall see hereafter, that many of the theorems in the higher geometry belong to the same class of propositions. We may add, that some of the elementary propositions of geometry want only the proper form of enunciation to be perfect porisms. It is not therefore strictly true, that none of the propositions called porisms have been known to the moderns; but it is certain, that they have not met, from them, with the attention they met with from the ancients, and that they have not been distinguished as a separate class of propositions. The cause of this difference is undoubtedly to be sought for in a comparison of the methods employed for the solution of geometrical problems in ancient and modern times.

" In the solution of such problems, the geometers of antiquity proceeded with the utmost caution, and were careful to remark every particular case, that is to say, every change in the construction, which any change in the state of the data could produce. The different conditions from which the solutions were derived, were supposed to vary one by one, while the others remained the same; and all their possible combinations being thus enumerated, a separate solution was given, wherever any considerable change was observed to have taken place.

" This was so much the case, that the Sectio Rationis, a geometrical problem of no great difficulty, and one of which the solution would be dispatched, according to the methods of the modern geometry, in a single page, was made by Apollonius, the subject of a treatise consisting of two books. The first book has 7 general divisions, and 24 cases; the second, 14 general divisions, and 73 cases, each of which cases is separately considered. Nothing, it is evident, that was any way connected with the problem, could escape a geometer, who proceeded with such minuteness of investigation.

" The same scrupulous exactness may be remarked in all the other mathematical researches of the ancients; and the reason doubtless is, that the geometers of those ages, however expert they were in the use of their analysis, had not sufficient experience in its powers, to trust to the more general applications of it. That principle which we call the law of continuity, and which connects the whole system of mathematical truths by a chain of insensible gradations, was scarcely known to them, and has been unfolded to us, only by a more extensive knowledge of the mathematical sciences, and by that most perfect mode of expressing the relations of quantity, which forms the language of algebra; and it is this principle alone which has taught us, that though in the solution of a problem, it may be impossible to conduct the investigation without assuming the data in a particular state, yet the result may be perfectly general, and will accommodate itself to every case with such wonderful versatility, as is scarcely credible to the most experienced mathematician, and such as often forces him to stop, in the midst of his calculus, and look back, with a mixture of diffidence and admiration, on the unforeseen harmony of his conclusions. All this was unknown to the ancients; and therefore they had no resource, but to apply their analysis separately to each particular case, with that extreme caution which has just been described; and in doing so, they were likely to remark many peculiarities, which more extensive views, and more expeditious methods of investigation, might perhaps have induced them to overlook.

" To rest satisfied, indeed, with too general results, and not to descend sufficiently into particular details, may be considered as a vice that naturally arises out of the excellence of the modern analysis. The effect which this has had, in concealing from us the class of propositions we are now considering, cannot be better illustrated than by the example of the porism discovered by Boscovich, in the manner related above. Though the problem from which that porism is derived, was resolved by several mathematicians of the first eminence, among whom also was sir Isaac Newton, yet the porism which, as it happens, is the most important case of it, was not observed by any of them. This is the more remarkable, as Sir Isaac Newton takes notice of the two most simple cases, in which the problem obviously admits of innumerable solutions, viz, when the lines given in position are either all parallel, or all meeting in a point, and these two hypotheses he therefore expressly excepts. Yet he did not remark, that there are other circumstances which may render the solution of the problem indeterminate as well as these; so that the porismatic case considered above, escaped his observation: and if it escaped the observation of one who was accustomed to penetrate so far into matters infinitely more obscure, it was because he satisfied himself with a general construction, without pursuing it into its particular cases. Had the solution been conducted after the manner of Euclid or Apollonius, the porism in question must infallibly have been discovered."

In the "Account of the Life and Writings of Rob. Simson, M. D." published in 1813, by the Rev. Dr. Wm. Trail, we find many learned observations on the subject of porisms. After a particular account of the labours of many authors on this subject, from Euclid and others among the ancients down to Pappus and Proclus, and the attempts at restoration by many of the moderns, but chiefly by Dr. Simson, Dr. Trail says,

"After a certain progress in the prosecution of this subject, it became an important object to ascertain a just definition of the porism. The definition given by the later mathematicians, as stated by Pappus, but censured by him, 'quod deficit hypothesi a theoremate locali,' clearly implies that a porism had an immediate reference to a locus; though it is not less clear that Pappus considered loci as only one class of porisms, (a large one no doubt,) but that of course many porisms have no connexion whatever with loci.

"But the definition which Pappus quotes from the ancients (viz, that it is something proposed to be investigated), as more characteristic of porisms, is too general for any useful purpose; and though it does correspond to the nature of these propositions, yet it is deficient in discrimination, and of itself neither conveys any precise notion of Euclid's porisms, nor gives assistance to the investigation of any individual proposition.

"After much consideration of various forms of a definition which had occurred to him, the doctor finally settled the following: 'A porism is a proposition in which it is proposed to demonstrate that some one or more things are given, to which, as also to every one of innumerable other things, not indeed given, but having the same relation to those that are given, it is to be shown that there belongs some common affection described in the proposition.'

"The doctor illustrates the propriety and accuracy of this definition by many examples; and shows particularly wherein the definition blamed by Pappus coincides with his, and wherein it is deficient, by excluding many genuine porisms. The definition indeed, with much address, is so framed as to correspond with all the intimations of Pappus respecting porisms, and also with the character of the individual porisms of Euclid, which Dr. Simson had discovered; and therefore may justly be considered as expressive of the notions on this subject entertained by the ancients. It is not pretended that this was a definition of the ancients; for probably no precise definition was given by them, of either theorem, problem or porism. None appears in the works of the more early geometers, which are still preserved in a considerable degree of purity, and where such definitions would naturally have had a place. And we may affirm with much probability, that if any useful and characteristic definition of a porism had reached the times of Pappus, he would not have neglected so valuable a remnant of ancient mathematical science, in a work obviously designed for the preservation of the more curious portions of it. He does not omit a definition, which probably was only a traditional and pointed observation of some ancient geometer, and though of no use in explaining the character of a porism, yet it in some degree fortified his objection to the definition of the later mathematicians, who, he states, from inability, could not accomplish the investigation of porisms; but satisfied themselves with assuming the constructions as they found them in Euclid, or other geometers, and adding the demonstrations.

"It is observed by Pappus, that a porism is neither a problem nor a theorem, but something of an intermediate nature; and that it might be proposed either as a problem or as a theorem; some geometers contending for the one, and some for the other. Dr. Simson has given a form to the enunciation of a porism, implying this intermediate character between a problem and a theorem. In his enunciation it is affirmed that certain things *may* be found, which shall have the relations or properties therein described. Perhaps this form resembles more that of a theorem, than of a problem; but at the same time, the things, of which it is said that they may be found, must be actually investigated by analysis, as if the proposition were a problem. Were it simply proposed to investigate certain things which would have the proporoties expressed in the porism, it may be regarded as a problem; but if these things are found by a construction described in the enunciation, the proposition becomes a theorem, affirming the truth of the properties asserted; and then a demonstration only is required, without any investigation; in the manner which appears to have been practised by the later mathematicians, alluded to by Pappus.

"I cannot omit adverting in this place to a very ingenious theory of porisms proposed by Mr. professor Playfair of Edinburgh, first briefly in his account of the life of Dr. Stewart, and afterwards more fully explained in a memoir on that subject in the 3d volume of the Transactions of the Royal Society of Edinburgh. The result of his investigation is, that a porism is the case of a problem which becomes indeterminate; or more particularly 'a porism is a proposition affirming the possibility of finding such conditions as will render a certain problem indeterminate, or capable of innumerable solutions.' But though I admire the ingenuity, and fully admit the soundness, of this definition, and also the utility of the principle on which it is founded, in the discovery of porisms, I must acknowledge my doubt of that particular notion of a porism having ever been adopted, or even proposed, among the ancient geometricians. The circumstance of its being so satisfactory as a definition, is to me a proof that it was never generally known or embraced: for had it ever been approved and established, it seems scarce possible that it should afterwards have been neglected and lost. That, among the ancients, the consideration of the relations subsisting among the data, in some problems, might have occasionally suggested the particular case in which these problems would become indeterminate, is very probable. It might also have often occurred to them, that this indeterminate case involved an important general proposition, which might be separately stated as such, and preserved. Many porisms of Euclid may possibly have been invented in that way; but still I entertain a doubt, if ever the ancients were in possession of this notion as a principle, and as the proper ground of the definition of a porism. Pappus mentions the definition of the ancients, and apparently as the only one which they were known to possess, though, as has been remarked, it be of no particular use. He mentions also a definition of the later mathematicians, which he censures as erroneous: but, if such a complete and satisfactory definition, which not only accurately distinguishes that class of propositions, but points out an obvious source of the discovery of them, had ever been generally understood among the ancients, it is difficult to suppose that it could ever have been lost; and had it reached the time of Pappus, it is most improbable that he should neglect the recording of it in his detailed account of Euclid's treatise on this subject. With these strong internal probabilities, and the total want of external evidence, I must (with deference, however, to the opinion of those who may think differently) adhere to the judgment which I have already expressed, concerning the recent origin of this excellent definition, proposed by Mr. Playfair."

On this subject, see also several other places in Dr. Trail's works, particularly the note D, pa. 88.

PORISM was also used in another sense, by the ancient geometricians, and even down to near the 17th century, to denote the same thing as the common corollary.

PORISTIC *Method*, is that which determines when, and by what means, and how many different ways, a problem may be resolved.

PORTA (JOHN BAPTISTA), called also in Italy Giovan Batista de la Porta, of Naples, flourished about the end of the 16th century, and was famous for his skill in philosophy, mathematics, medicine, natural history, &c, as well as for his indefatigable endeavours to improve and propagate the knowledge of those sciences. With this view, he not only established private schools for particular sciences, but to the utmost of his power promoted public academies. He had no small share in establishing the academy at Gli Ozioni, at Naples, and had one in his own house, called de Secreti, into which none were admitted members, but such as had made some new discoveries in nature. He invented the camera obscura, improved afterwards by Gravesande, and formed the plan of an encyclopædia. He died at Pisa, in the kingdom of Naples, in the year 1615. Porta gave the fullest proof of an extensive genius, and wrote a great many works; the principal of which are as follow:

1. His Natural Magic; a book abounding with curious experiments; but containing nothing of magic, in the common acceptation of the word, as he pretends to nothing above the power of nature.
2. Elements of Curve Lines.
3. A Treatise of Distillation.
4. A Treatise of Arithmetic.
5. Concerning Secret Letter-writing.
6. Of Optical Refractions.
7. A Treatise of Fortification.
8. A Treatise of Physiognomy.

Beside some Plays and other pieces of less note.

PORTAIL, in Architecture, the face or frontispiece of a church, viewed on the side in which the great door is placed. It means also the great door or gate itself of a palace, castle, &c.

PORTAL, in Architecture, a term used for a little square corner of a room, cut off from the rest of the room by the wainscot; frequent in the ancient buildings, but now disused.

PORTAL is sometimes also used for a little gate, portella; where there are two gates, a large and a small one.

PORTAL is sometimes also used for a kind of arch of joiner's work before a door.

PORTCULLICE, called also *Herse*, and *Sarrasin*, in Fortification, an assemblage of several large pieces of wood laid or joined across one another, like a harrow, and each pointed at the bottom with iron. These were formerly used to be hung over the gateways of fortified places, to be ready to let down in case of a surprise, when the enemy should come so quick, as not to allow time to shut the gates. But the orgues are now more generally used, being found to answer the purpose better.

PORT-FIRE, in Gunnery, a paper tube, about 10 inches long, filled with a composition of meal-powder, sulphur, and nitre, rammed moderately hard; used to fire guns and mortars, instead of a match.

PORTICO, in Architecture, is a kind of gallery, raised upon arches, under which people walk for shelter.

POSITION, or *Site*, or *Situation*, in Physics, is an affection of place, expressing the manner of a body's being in it.

POSITION, in Architecture, denotes the situation of a building, with respect to the points of the horizon. The best it is thought is when the four sides point directly to the four winds, or cardinal points.

POSITION, in Astronomy, relates to the sphere. The position of the sphere is either right, parallel, or oblique; whence arise the inequality of days, the difference of seasons, &c.

Circles of POSITION, are circles passing through the common intersections of the horizon and meridian, and through any degree of the ecliptic, or the centre of any star, or other point in the heavens; used for finding out the position or situation of any star. These are usually counted six in number, cutting the equator into twelve equal parts, which the astrologers call the celestial houses.

POSITION, in Arithmetic, called also False Position, or Supposition, or Rule-of-False, is a rule so called, because it consists in calculating by false numbers, supposed or taken at random, according to the process described in any question or problem proposed, as if they were the true numbers, and then from the results, compared with that given in the question, the true numbers are found. It is sometimes also called Trial-and-Error, because it proceeds by trials of false numbers, and thence finds out the true ones by a comparison of the errors.—Position is either single or double.

Single POSITION is when only one supposition is employed in the calculation. And *Double* POSITION is that in which two suppositions are employed.—To the rule of position properly belong such questions as cannot be resolved from a direct process by any of the other usual rules in arithmetic, and in which the required numbers do not ascend above the first power: such, for example, as most of the questions usually brought to exercise the reduction of simple equations in algebra. But it will not bring out true answers when the numbers sought ascend above the first power; for then the results are not proportional to the positions, or supposed numbers, as in the single rule; nor yet the errors to the difference of the true number and each position, as in the double rule. Yet in all such cases, it is a very good approximation, and in exponential equations, as well as in many other things, it succeeds better than perhaps any other method whatever.

Those questions, in which the results are proportional to their suppositions, belong to single position: such are those which require the multiplication or division of the number sought by any number; or in which it is to be increased or diminished by itself any number of times, or by any part or parts of it. But those in which the results are not proportional to their positions, belong to the double rule: such are those, in which the numbers sought, or their multiples or parts, are increased or diminished by some given absolute number, which is no known part of the number sought.

In Single Position. Suppose, or assume any number at pleasure, for the number sought, and proceed with it as if it were the true number, that is, perform the same operations with it as, in the question, are described to be performed with the number sought: then if the result of those operations be the same with that mentioned or given in the question, the supposed number is the same as the true one that was required; but if it be not, make this proportion, viz, as the result is to that in the question, so is the supposed false number, to the true one required.

Example. Suppose that a person, after spending $\frac{1}{3}$ and $\frac{1}{4}$ of his money, has yet remaining 60*l.*; what sum had he at first?

Suppose he had at first 120*l.*

Now $\frac{1}{3}$ of 120 is	40
and $\frac{1}{4}$ of it is	30
their sum is	70
which taken from	120
leaves remaining	50, instead of 60.

Therefore as 50 : 60 : : 120 : 144 the sum at first.

Proof.	$\frac{1}{3}$ of 144 is	48
	$\frac{1}{4}$ of it is	36
	their sum	84
	taken from	144
	leaves just	60 as per quest.

To work by the Double Rule of Position.

In this rule, make two different suppositions, or assumptions, and work or perform the operations with each, described in the question, exactly as in the single rule: and if neither of the supposed numbers solve the question, that is, produce a result agreeing with that in the question; then observe the errors, or how much each of the false results differs from the true one, and also whether they are too great or too little; marking them with + when too great, and with − when too little. Next multiply, crosswise, each position by the error of the other; and if the errors be of the same affection, that is both +, or both −, subtract the one product from the other, as also the one error from the other, and divide the former of these two remainders by the latter, for the answer, or number sought. But if the errors be unlike, that is, the one +, and the other −, add the two products together, and also the two errors together, and divide the former sum by the latter, for the answer.

Rule 2. Multiply the difference of the two assumed numbers by one of the errors, and divide the product by the difference of the results, the quotient will be the correction of the assumed number belonging to that error: Then add this quotient or correction to the said assumed number when it is too small, but subtract it when too great, to give the answer.

This rule of position, or trial-and-error, is a good general way of approximating to the roots of the higher equations, to which it may be applied even before the equation is reduced to a final or simple state, by which it often saves much trouble in such reductions. It is also eminently useful in resolving exponential equations, and equations involving arcs, or sines, &c, or logarithms, and in short in any equations that are very intricate and difficult. And even in the extraction of the higher roots of common numbers, it may be very usefully applied. For examples, and the demonstration of the rules, see the 1st vol. of my Course of Mathematics.

The rule of position passed from the Moors into Europe, by Spain and Italy, along with their algebra, or method of equations, which was probably derived from the former.

Position, in Geometry, respects the situation, bearing, or direction of one thing, with regard to another. And Euclid says, "Points, lines, and angles, which have and keep always one and the same place and situation, are said to be given by position or situation." Data, def. 4.

POSITIVE *Quantities*, in Algebra, such as are of a real, affirmative, or additive nature; and which either have, or are supposed to have, the affirmative or positive sign + before them; as *a* or + *a*, or *bc*, &c. It is used in contradistinction from negative quantities, which are defective or subductive ones, and marked by the sign −; as − *a*, or − *ab*.

Positive *Electricity.* In the Franklinian system, all bodies supposed to contain more than their natural quantity of electric matter, are said to be positively electrified; and those which have less than that quantity, are said to be electrified negatively. These two electricities being at first produced, the one from glass, the other from amber or rosin, the former was called vitreous, the other resinous electricity.

POSTERN, or *Sally-port*, in Fortification, a small gate, usually made in the angle of the flank of a bastion, or in that of the curtain, or near the orillon, descending into the ditch; by which the garrison can march in and out, unperceived by the enemy, either to relieve the works, or to make private sallies, &c.—It means also any private or back door.

POSTICUM, in Architecture, the postern gate, or back-door of any fabric.

POSTULATE, a demand, petition, or an assertion of so obvious a nature, as to need neither demonstration nor explication, to render it either more plain or certain. This definition will nearly agree also to an axiom, which is a self-evident theorem, as a postulate is a self-evident problem.—Euclid lays down these three postulates in his Elements; viz, 1st, That from one point to another a line can be drawn. 2d, That a right line can be produced out at at pleasure. 3d, That with any centre and radius a circle may be described.—As to axioms, he has a great number; as, That two things which are equal to one and the same thing, are equal to each other, &c.

POTASH, in chemistry, one of the three fixed alkalies, procured from the burnt ashes of vegetables, by combustion in iron or other pots; whence the compound pot-ash.

POTASSIUM, a recently discovered and very singular metal, obtained by peculiar management, from pot-ash, which in modern chemistry can only be regarded as its oxyd.

POUND, a certain weight; which is of two kinds, viz, the pound troy, and the pound avoirdupois; the former consisting of 12 ounces troy, and the latter of 16 ounces avoirdupois. The pound troy is to the pound avoirdupois as 5760 to 6999¼, or nearly 576 to 700.

POUND also is an imaginary money used in accounting, in several countries. Thus, in England there is the pound sterling, containing in value 20 shillings; in France the pound or livre Tournois and Parisis; in Holland and Flanders, a pound or livre de gros, &c.—The term arose from hence, that the ancient pound sterling, though it only contained 240 pence, as ours does; yet each penny being equal to five of ours, the pound of silver weighed a pound troy.

POUNDER, in Artillery, a term used to express a certain weight of shot or ball, or how many pounds weight the proper ball is for any cannon: as a 24 pounder, a 12 pounder, &c.

POWDER, *Gun.* See GUNPOWDER.

POWDER-*Triers.* See EPROUVETTE.

POWER, in Mechanics, denotes some force which, being applied to a machine, tends to produce motion; whether it does actually produce it or not. In the former case, it is called a moving power; in the latter, a sustaining power.

POWER is also used in Mechanics, for any of the six simple machines, viz, the lever, the balance, the screw, the wheel and axle, the wedge, and the pulley.

POWER *of a Glass*, in Optics, is used for the distance between the convexity and the solar focus.

POWER, in Arithmetic, the produce of a number, or other quantity, arising by multiplying it by itself, any number of times. Any number is called the first or single power of itself. If it be multiplied once by itself, the product is the second power, or square; if this be multiplied by the first power again, the product is the third power, or cube; if this be multiplied by the first power again, the product is the fourth power, or biquadratic; and so on; the power being always denominated from the number which exceeds the multiplications by one or unity, which number is called the index or exponent of the power, and is usually set at the upper corner towards the right of the given quantity or root, to denote or express the power.

Thus, 3 or $3^1 = 3$ is the 1st power of 3,
3×3 or $3^2 = 9$ is the 2d power of 3,
$3^2 \times 3$ or $3^3 = 27$ is the 3d power of 3,
$3^3 \times 3$ or $3^4 = 81$ is the 4th power of 3,
&c. &c.

Hence, to raise a quantity to a given power, is the same as to find the product arising from its being multiplied by itself a certain number of times; for example to raise 2 to the 3d power, is the same thing as to find the factum, or product $8 = 2 \times 2 \times 2$. The operation of raising powers, is called Involution.

Powers, of the same degree, are to one another in the ratio of the roots as manifold as their common exponent contains units: thus, squares are in a duplicate ratio of the roots; cubes in a triplicate ratio; 4th powers in a quadruplicate ratio.—And the powers of proportional quantities are also proportional to one another: so, if $a : b :: c : d$, then, in any powers also, $a^n : b^n :: c^n : d^n$.

The particular names of the several powers, as introduced by the Arabians, were, square, cube, quadratoquadratum or biquadrate, sursolid, cube squared, second sursolid, quadrato-quadrato-quadratum, cube of the cube, square of the sursolid, third sursolid, and so on, according to the *products* of the indices.

And the names given by Diophantus, who is followed by Vieta and Oughtred, are, the side or root, square, cube, quadrato-quadratum, quadrato-cubus, cubo-cubus, quadrato-quadrato-cubus, quadrato-cubo-cubus, cubo-cubo-cubus, &c, according to the *sums* of the indices.

But the moderns, after Harriot and Descartes, are contented to distinguish most of the powers by the exponents; as 1st, 2d, 3d, 4th, &c.

The characters by which the several powers are denoted, both in the Arabic and Cartesian notation, are thus:

Arab.	1	*R*	*q*	*c*	*bq*	*s*	*qc*	*Bs*	*tq*	*bc*
Cart.	a^0	a^1	a^2	a^3	a^4	a^5	a^6	a^7	a^8	a^9
	1	2	4	8	16	32	64	128	256	512

Hence, 1st. The powers of any quantity, form a series of geometrical proportionals, and their exponents a series of arithmetical proportionals, in such sort that the addition of the latter answers to the multiplication of the former, and the subtraction of the latter answers to the division of the former, &c; or in short, that the latter, or exponents, are as the logarithms of the former, or powers.

Thus, $a^2 \times a^3 = a^5$, and $2 + 3 = 5$;
$4 \times 8 = 32$;
also $a^5 \div a^3 = a^2$, and $5 - 3 = 2$;
$32 \div 8 = 4$.

2d. The 0 Power of any quantity, as a^0, is $= 1$.

3d. Powers of the same quantity are multiplied, by adding their exponents: Thus,

Mult.	a^3	x^2	y^m	x^m	a^3
by	a^4	x^4	y^m	x^n	a^n
Prod.	a^7	x^6	y^{2m}	x^{m+n}	a^{3+n}

4th. Powers are divided by subtracting their exponents.

Div.	a^7	x^6	y^{2m}	x^{m+n}	a^{3+n}
by	a^3	x^2	y^m	x^m	a^3
Quot.	a^4	x^4	y^m	x^n	a^n

5th. Powers are also considered as negative ones, or having negative exponents, when they denote a divisor, or the denominator of a fraction. So $\frac{1}{a^3} = a^{-3}$, and $\frac{2}{a^3} = 2a^{-3}$, and $\frac{a^2}{x^4} = a^2x^{-4}$, &c. And hence any quantity may be changed from the denominator to the numerator, or from a divisor to a multiplier, or vice versa, by changing the sign of its exponent; and the whole series of powers proceeds indefinitely both ways from 1 or the 0 power, positive on the one hand, and negative on the other. Thus,

$$\&c\ a^{-4}\ a^{-3}\ a^{-2}\ a^{-1}\ a^0\ a^1\ a^2\ a^3\ a^4\ \&c,$$

$$\text{or, } \&c\ \frac{1}{a^4}\ \ \frac{1}{a^3}\ \ \frac{1}{a^2}\ \ \frac{1}{a}\ \ 1\ \ a\ \ a^2\ a^3\ a^4\ \&c.$$

Powers are also denoted with fractional exponents, or even with surd or irrational ones; and then the numerator denotes the power raised to, and the denominator the exponent of some root to be extracted: Thus,

$\sqrt{a} = a^{\frac{1}{2}}$, and $\sqrt{a^3} = a^{\frac{3}{2}}$, and $\sqrt[3]{a^2} = a^{\frac{2}{3}}$, &c. These are sometimes called imperfect powers, or surds.

When the quantity to be raised to any power is positive, all its powers must be positive. And when the radical quantity is negative, yet all its even powers must be positive: because $-\times-$ gives $+$: the odd powers only being negative, or when their exponents are odd numbers: Thus, the powers of $-a$,

are $+ 1, - a, + a^2, - a^3, + a^4, - a^5, + a^6$, &c.
where the even powers a^2, a^4, a^6 are positive,
and the odd powers a, a^3, a^5 are negative.

Hence, if a power have a negative sign, no even root of it can be assigned; since no quantity multiplied by itself an even number of times, can give a negative product. Thus $\sqrt{-a^2}$, or the square or 2d root of $-a^2$, cannot be assigned; and is called an impossible root, or an imaginary quantity. Every power has as many roots, real and imaginary, as there are units in the exponent.

M. Lahire gives a very odd property common to all powers. M. Carré had observed with regard to the number 6, that all the natural cubic numbers, 8, 27, 64, 125, having their roots less than 6, being divided by 6, the remainder of the division is the root itself; and if we go farther, 216, the cube of 6, being divided by 6, leaves no remainder; but the divisor 6 is itself the root. Again, 343, the cube of 7, being divided by 6, leaves 1; which added to the divisor 6, makes the root 7, &c. M. Lahire, on considering this, has found that all numbers, raised to any power whatever, have divisors, which have the same effect with regard to them, that 6 has with regard to cubic numbers. For finding these divisors, he discovered the following general rule, viz, If the exponent of the power of a number be even, i. e. if the number be raised to the 2d, 4th, 6th, &c, power, it must be divided by 2; the remainder of the division, when there is any, added to 2, or to a multiple of 2, gives the root of this number, corresponding to its power, i. e. the 2d, 4th, 6th, &c root.

But if the exponent of the power be an uneven number, i. e. if the number be raised to the 3d, 5th, 7th, &c power; the double of this exponent will be the divisor, which has the property abovementioned. Thus is it found in 6, the double of 3, the exponent of the power of the cubes: so also 10, the double of 5, is the divisor of all 5th powers; &c.

If r be a prime number, and n any number not divisible by r, then n^r, being divided by r, will leave the same remainder, as n when divided by the same number: and hence it follows that $\frac{n^r - n}{r}$ is always an integer; and since n is prime to r, therefore $\frac{n^{r-1} - 1}{r}$ is always an integer when r is a prime number and n prime to r. This is a very important theorem in the theory of numbers, the invention of which is due to Fermat, though the demonstration of it was first given by Euler in the Petersburg Memoirs.

By means of this theorem we readily deduce the following table of the forms of powers, with regard to certain numbers taken as moduli. Thus all

2nd powers are of the form	$5n$	or	$5n \pm 1$
3d powers - - - - -	$7n$	or	$7n \pm 1$
4th powers - - - - -	$5n$	or	$5n + 1$
5th powers - - - - -	$11n$	or	$11n + 1$
6th powers - - - - -	$13n$	or	$13n \pm 1$
8th powers - - - - -	$17n$	or	$17n \pm 1$
9th powers - - - - -	$19n$	or	$19n \pm 1$
10th powers - - - - -	$11n$	or	$11n \pm 1$
11th powers - - - - -	$23n$	or	$23n \pm 1$
12th powers - - - - -	$13n$	or	$13n + 1$

And generally if $m + 1$ is a prime number, then x^m is of one of the forms $(m + 1)n$ or $(m + 1)n + 1$. And if $2m + 1$ be a prime, then x^m is of one of the three forms $(m + 1)n$ or $(m + 1)n \pm 1$. And since neither $7 + 1$ nor $2.7 + 1$ is a prime, therefore 7th powers cannot be reduced to the laws observed in the foregoing table, for which reason this power is there omitted.

Any power of the natural numbers 1, 2, 3, 4, 5, 6, &c, as the nth power, has as many orders of differences as there are units in the common exponent of all the numbers; and the last of those differences is a constant quantity, and equal to the continual product $1 \times 2 \times 3 \times 4 \times$ ------ $\times n$, continued till the last factor, or the number of factors, be n, the exponent of the powers. Thus,

the 1st powers, 1, 2, 3, 4, 5, &c, have but one order
of differences 1 1 1 1 &c, and that difference is 1.
The 2d pwrs. 1, 4, 9, 16, 25, &c, have two orders of
differences 3 5 7 9
2 2 2
and the last of these is $2 = 1 \times 2$.
The 3d pwrs. 1, 8, 27, 64, 125, &c, have three orders
of differences 7 19 37 61
12 18 24
6 6
and the last of these is $6 = 1 \times 2 \times 3$.

In like manner, the 4th or last differences of the 4th powers, are each $24 = 1 \times 2 \times 3 \times 4$; and the 5th or last differences of the 5th powers, are each $120 = 1 \times 2 \times 3 \times 4 \times 5$. And so on. Which property was first noticed by Peletarius.

And the same is true of the powers of any other arithmetical progression $1, 1 + d, 1 + 2d, 1 + 3d$, &c,
viz, $1, (1 + a)^n, (1 + 2d)^n, (1 + 3d)^n$, &c,
the number of the orders of differences being still the same exponent n, and the last of those orders each equal to $1 \times 2 \times 3$ ------ $\times nd^n$, the same product of factors as before, multiplied by the same power of the common difference d of the series of roots: as was shown by Briggs.

And hence arises a very easy and general way of raising the powers of all the natural numbers, viz, by common addition only, beginning at the last differences, and adding them all continually, one after another, up to the powers themselves. Thus, to generate the series of cubes, or 3d powers, adding always 6, the common 3d difference gives the 2d differences 12, 18, 24, &c; and these added to the 1st of the 1st differences 7, gives the rest of the said 1st differences; and these again added to the 1st cube 1, gives the rest of the series of cubes, 8, 27, 64, &c, as below.

			&c.

Commensurable in POWER, is said of quantities which, though not commensurable themselves, have their squares, or some other power of them, commensurable. Euclid confines it to squares. Thus, the diagonal and side of a square are commensurable in power, their squares being as 2 to 1, or commensurable; though they are not commensurable themselves, being as $\sqrt{2}$ to 1.

POWER *of an Hyperbola*, is the square of the 4th part of the conjugate axis.

PRACTICAL Arithmetic, Geometry, Mathematics,

&c, is the part that regards the practice, or application, as distinguished from the theoretical part.

PRACTICE, in Arithmetic, is a rule which expeditiously and compendiously answers questions in the golden rule, or rule-of-three, especially when the first term is 1. See rules for this purpose in all the books of practical arithmetic.

PRECESSION *of the Equinoxes*, is a very slow motion of them, by which they change their place, going from east to west, or backward, *in antecedentia*, as astronomers call it, or contrary to the order of the signs. From the late improvements in astronomy it appears, that the pole, the solstices, the equinoxes, and all the other points of the ecliptic, have a retrograde motion, and are constantly moving from east to west, or from Aries towards Pisces, &c; by means of which, the equinoctial points are carried farther and farther back, among the preceding signs or stars, at the rate of about 50″¼ each year; which retrograde motion is called the Precession, Recession, or Retrocession of the Equinoxes.

Hence, as the stars remain nearly immoveable, and the equinoxes go backward, the stars will seem to move more and more eastward with respect to them; for which reason the longitudes of all the stars, being reckoned from the first point of Aries, or the vernal equinox, are continually increasing. From this cause it is, that the constellations seem all to have changed the places assigned to them by the ancient astronomers. In the time of Hipparchus, and the oldest astronomers, the equinoctial points were fixed to the first stars of Aries and Libra: but the signs do not now answer to the same points; and the stars which were then in conjunction with the sun when he was in the equinox, are now a whole sign, or 30 degrees, to the eastward of it: so, the first star of Aries is now in the portion of the ecliptic, called Taurus; and the stars of Taurus are now in Gemini; and those of Gemini in Cancer; and so on.

This seeming change of place in the stars was first observed by Hipparchus of Rhodes, who, 128 years before Christ, found that the longitudes of the stars in his time were greater than they had been before observed by Timochares, and than they were in the sphere of Eudoxus, who wrote 380 years before Christ. Ptolemy also perceived the gradual change in the longitudes of the stars; but he stated the quantity at too little, making it but 1° in 100 years, which is at the rate of only 36″ per year. Y-hang, a Chinese, in the year 721, stated the quantity of this change at 1° in 83 years, which is at the rate of 43″⅜ per year. Other more modern astronomers have made this precession still more, but with some small differences from each other; and it is now usually taken at 50″¼ per year. All these rates are deduced from a comparison of the longitude of certain stars as observed by more ancient astronomers, with the later observations of the same stars; viz, by subtracting the former from the latter, and dividing the remainder by the number of years in the interval between the dates of the observations. Thus, by a medium of a great number of comparisons, the quantity of the annual change has been fixed at 50″¼.

Thus, by taking the longitudes of the principal stars established by Tycho Brahé, in his book Astronomiæ Instauratæ Progymnasmata, pa. 208 and 232, for the beginning of 1586, and comparing them with the same as determined for the year 1750, by M. Lacaille, for that interval of 164 years, there will be obtained the following differences of longitude of several stars; viz,

γ Arietis	2°	17′	37″
Aldebaran	2	17	45
μ Geminorum	2	17	1
β Geminorum	2	15	26
Regulus	2	16	32
α Virginis	2	18	18
α Aquilæ	2	19	1
α Pegasi	2	16	12
β Libræ	2	17	52
Antares	2	16	28
ε Tauri	2	17	58
γ Geminorum	2	18	38
γ Cancri	2	19	12
γ Leonis	2	19	38
γ Capricorni	2	16	10
Medium of these 15 stars	2	17	35

which divided by 164, the interval of years, gives 50″·336, or nearly 50″⅓, or after the rate of 1° 23′ 53″⅓ in 100 years. And nearly the same conclusion results from the longitudes of the stars in the Britannic catalogue, compared with those of the still later catalogue. See Lalande's Astronomy, in several places.

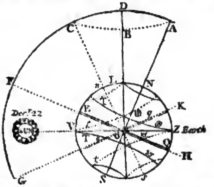
Mr. Mayer, in the construction of his tables, assumed the precession of the equinoxes, or the annual motions of the fixed stars in longitude, to be exactly 50″·3, without paying any regard to the alteration of the place of the equinox arising from the translation of the plane of the ecliptic by the action of the planets. Dr. Bradley, by comparing his own observations of declinations of stars, lying on both sides of the equinoctial colure, with the like observations of Tycho Brahé, found the precession of the equinoxes in longitude, to be exactly 1° in 71½ years, or at the rate of 50″·35 in a year, which is evidently what arises from the motion of the plane of the equator alone, being that which is occasioned by the actions of the sun and moon on the spheroidal figure of the earth. But the equinoctial point is also altered, though in a far less degree, by the continual motion of the plane of the ecliptic, owing to the action of the planets, and goes forward 0″·15 in a year, from that cause, along the ecliptic, which will diminish the precession of the equinoxes, on the apparent annual motions of the fixed stars, lying near the plane of the ecliptic, in longitude as much, and so reduce them from 50″·35 to 50″·20 or 50″⅕. See Naut. Ephemer. for 1797, the preface.

Taking therefore 50″⅕ for the true mean annual precession of the equinoxes, at this rate it will require 25,816⅔ years for the equinoxes to make their revolution westward quite around the circle, and return to the same point again.

The ancients, and even some of the moderns, have taken the equinoxes to be immoveable; and ascribed that change in the distance of the stars from it, to a real motion of the orb of the fixed stars, which they supposed had a slow revolution about the poles of the ecliptic; so as that all the stars perform their circuits in the ecliptic, or its parallels, in the space of 25,791 years; after which they should all return again to their former places.

This period the ancients called the Platonic, or great year; and imagined that at its completion every thing would begin as at first, and all things come round in the same order as they have done before.

The phenomena of this retrograde motion of the equinoxes, or intersections of the equinoctial with the ecliptic, and consequently of the conical motion of the earth's axis, by which the pole of the equator describes a small circle in the same period of time, may be understood and illustrated by a scheme, as follows: Let NZSVL be the earth, SONA its axis produced to the starry heavens, and terminating in A, the present north pole of the heavens, which is vertical to N, the north pole of the earth. Let EOQ be the equator, T♋Z the tropic of cancer, and VT♑ the tropic of Capricorn; VOZ the ecliptic, and BO its axis, both of which are immoveable among the stars. But as the equinoctial points recede in the ecliptic, the earth's axis SON is in motion upon the earth's centre O, in such a manner as to describe the double cone NON and SOS, round the axis of the ecliptic BO, in the time that the equinoctial points move round the ecliptic, which is 25,791 years; and in that length of time, the north pole of the earth's axis, produced, describes the circle ABCDA in the starry heavens, round the pole of the ecliptic, which keeps immoveable in the centre of that circle. The earth's axis being now 23° 28′ inclined to the axis of the ecliptic, the circle ABCDA, described by the north pole of the earth's axis produced to A, is 46° 56′ in diameter, or double the inclination of the earth's axis. In consequence of this, the point A, which is at present the north pole of the heavens, and near to a star of the 2d magnitude in the end of the Little Bear's tail, must be deserted by the earth's axis; which moving backwards 1 degree every 71⅔ years nearly, will be directed towards the star or point B in 6447¾ years hence; and in double of that time, or 12,895½ years, it will be directed towards the star or point C; which will then be the north pole of the heavens, though it is at present 8½ degrees south of the zenith of London L. The present position of the equator EOQ will then be changed into eoq, the tropic of cancer T♋Z into Vt♋, and the tropic of capricorn VT♑ into t♑z; as is evident by the figure. And the sun, in the same part of the heavens where he is now over the earthly tropic of capricorn, and makes the shortest days and longest nights in the northern hemisphere, will then be over the earthly tropic of cancer, and make the days longest and nights shortest. So that it will require 12,895½ years yet more, or from that time, to bring the north pole N quite round, so as to be directed toward that point of the heavens which is vertical to it at present. And then, and not till then, the same stars which at present describe the equator, tropics, and polar circles, &c, by the earth's diurnal motion, will describe them over again.



From this movement of the equinoctial points, and with them all the signs of the ecliptic, it follows, that those stars which in the infancy of astronomy were in Aries, are now found in Taurus; those of Taurus in Gemini, &c. Hence likewise it is, that the stars which rose or set at any particular season of the year, in the times of Hesiod, Eudoxus, Virgil, Pliny, &c, by no means answer at this time to their descriptions.

As to the physical cause of the precession of the equinoxes, sir Isaac Newton demonstrates, that it arises from the broad or flat spheroidal figure of the earth; which itself arises from the earth's rotation about its axis: for as more matter has thus been accumulated all round the equatorial parts, than any where else on the earth, the sun and moon, when on either side of the equator, by attracting this redundant matter, bring the equator sooner under them, in every return towards it, than if there were no such accumulation.

Sir Isaac Newton, in determining the quantity of the annual precession from the theory of gravity, on supposition that the equatorial diameter of the earth is to the polar diameter, as 230 to 229, finds the sun's action sufficient to produce a precession of 9″⅛ only; and collecting from the tides the proportion between the sun's force and the moon's to be as 1 to 4½, he settles the mean precession resulting from their joint actions, at 50″; which, it must be owned, is nearly the same as it has since been found by the best observations; and yet several other mathematicians have since objected to the truth of Newton's computation.

Indeed, to determine the quantity of the precession arising from the action of the sun, is a problem that has been much agitated among modern mathematicians; and though they seem to agree as to Newton's mistake in the solution of it, they have yet generally disagreed from one another. Dalembert, in 1749, printed a treatise on this subject, and claims the honour of having been the first who rightly determined the method of resolving problems of this kind. The subject has been also considered by Euler, Frisi, Silvabelle, Walmesley, Simpson, Emerson, Laplace, Lagrange, Landen, Milner, and Vince.

M. Silvabelle, stating the ratio of the earth's axis to be that of 178 to 177, makes

the annual precession caused by the sun 13″ 52‴,
and that of the moon - - 34 17;

making the ratio of the lunar force to the solar, to be that of 5 to 2; also the nutation of the earth's axis caused by the moon, during the time of a semirevolution of the pole of the moon's orbit, i. e. in 9⅓ years, he makes 17″ 51‴. —Walmesley, on the supposition that the ratio of the earth's diameters is that of 230 to 229, and the obliquity of the ecliptic to the equator 23° 28′ 30″, makes the annual precession, owing to the sun's force, equal to 10″·583; but supposing the ratio of the diameters to be that of 178 to 177, that precession will be 13″·675.—Mr. Simpson, by a different method of calculation, determines the whole annual precession of the equinoxes caused by the sun, at 21″ 6‴; and he has pointed out the errors of the computations proposed by Silvabelle and Walmesley.—Mr. Milner's deduction agrees with that of Mr. Simpson, as well as Mr. Vince's; and their papers contain besides several curious particulars relative to this subject. But for the various principles and reasonings of these mathematicians, see Philos. Trans. vol. 48, pa. 385; vol. 49, pa. 704; vol. 69, pa. 505; and vol. 77, pa. 363; as also the writings of Simpson, Emerson, Landen, &c; also Lalande's Astronomie, and the Memoirs of the Acad. Sci. in several places.

As to the effect of the planets on the equinoctial points, Laplace, in his new researches on this article, finds that their action causes those points to advance by 0″·2016 in a year, along the equator, or 0″·1849 along the ecliptic; whence it follows that the quantity of the luni-solar precession must be 50″·4349, since the total observed precession is 50″¼, or 50″·25.

To find the Precession in right ascension and declination.

Put $d =$ the declination of a star,

and $a =$ its right ascension;

then their annual variations of precessions will be nearly as follow:

viz, $20''·084 \times \cos. a =$ the annual preces. in declinat.

and $46''·0619 + 20''·084 \times \sin. a \times \text{tang. } d =$ that of right ascension. See the Connoissance des Temps for 1792, pa. 206, &c.

PRESS, in Mechanics, is a machine made of iron or wood, serving to compress or squeeze any body very close, by means of screws. The common presses consist of six members, or pieces; viz, two flat and smooth planks; between which the things to be pressed are laid; two screws, or worms, fastened to the lower plank, and passing through two holes in the upper; and two nuts, serving to drive the upper plank, which is moveable, against the lower, the latter being stable, and without motion.

PRESSION. See PRESSURE.

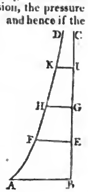
PRESSURE, is properly the action of a body which makes a continual effort or endeavour to move another; such as the action of a heavy body supported by a horizontal table; in contradistinction from percussion, or a momentary force or action. Pressure equally respects both bodies, that which presses, and that which is pressed; from the mutual equality of action and reaction.

Pressure, in the Cartesian philosophy, is an impulsive kind of motion, or rather an endeavour to move, impressed on a fluid medium, and propagated through it. In such a pressure the Cartesians suppose the action of light to consist. And in the various modifications of this pressure, by the surfaces of bodies, on which that medium presses, they suppose the various colours to consist, &c. But Newton shows, that if light consisted only in a pressure, propagated without actual motion, it could not agitate and warm such bodies as reflect and refract it, as we actually find it does; and if it consisted in an instantaneous motion, or one propagated to all distances in an instant, as such pressure supposes, there would be required an infinite force to produce that motion every moment, in every lucid particle. Further, if light consisted either in pressure, or in motion propagated in a fluid medium, whether instantaneously, or in time, it must follow, that it would inflect itself ad umbram; for pressure, or motion, in a fluid medium, cannot be propagated in right lines, beyond any obstacle which shall hinder any part of the motion; but will inflect and diffuse itself, every way, into those parts of the quiescent medium which lie beyond the said obstacle. Thus the force of gravity tends downward; but the pressure which arises from that force of gravity, tends every way with an equable force; and, with equal ease and force, is propagated in crooked lines, as in straight ones. Waves on the surface of water, while they slide by the sides of any large obstacle, do inflect, dilate, and diffuse themselves gradually into the quiescent water lying beyond the obstacle. The waves, pulses, or vibrations of the air, in which sounds consist, do manifestly inflect themselves, though not so much as the waves of water; for the sound of a bell, or of a cannon, can be heard over a hill, which intercepts the sonorous object from our sight; and sounds are propagated as easily through crooked tubes, as through straight ones. But light is never observed to go in curved lines, nor to inflect itself ad umbram; for the fixed stars do immediately disappear on the interposition of any of the planets; as well as some parts of the sun's body, by the interposition of the moon, or Venus, or Mercury.

PRESSURE *of Air, Water, &c.* See AIR, WATER, &c.

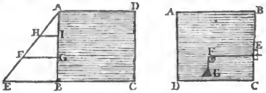
The effects anciently ascribed to the fuga vacui, are now accounted for from the weight and pressure of the air.

The pressure of the air on the surface of the earth, is balanced by a column of water of the same base, and about 34 feet high; or of one of mercury of near 30 inches high; and upon every square inch at the earth's surface, that pressure amounts to about 14¾ pounds avoirdupois. The elasticity of the air is equal to that pressure, and by means of that pressure, or elasticity, the air would rush into a vacuum with a velocity of about 1370 feet per second. At different heights above the earth's surface the pressure of the air is as its density and elasticity, and each decreases in such sort, that as the heights above the surface increase in arithmetical progression, the pressure &c decreases in geometrical progression: and hence if the axis BC of a logarithmic curve AD be erected perpendicular to the horizon, and if the ordinate AB denote the pressure, or elasticity, or density of the air, at the earth's surface, then will any other absciss



EF, GH, IK } denote the pressure &c at the altitude { BE, BG, BI,

The pressure of water, as this fluid is every-where of the same density, is as its depth at any place, and in all directions the same; and upon a square foot of surface, every foot in height presses with the force of a weight of 1000 ounces or 62½lbs. avoirdupois. And hence, if AB be the depth of



water in any vessel, and BE denote its pressure at the depth B; by joining AE and drawing any other ordinates FG, HI; then will these ordinates FG, HI, &c, denote the pressure at the corresponding depths AG, AI, &c; also the area of the triangle ABE will denote the whole pressure against the whole upright side AB and which therefore is but half the pressure on the bottom of the same area as the side. Moreover, if a hole were opened in the bottom or side of the vessel at B, the water, from the pressure of the superincumbent fluid, would issue out with the velocity of $8\sqrt{AB}$ feet per second nearly; AB being estimated in feet.

Pressure of Earth against Walls, &c. This is a circumstance of considerable importance, on many occasions, as in embankments, in fortifications, in docks, in piers, &c. The practice is to have the counterparts equal to, or rather to exceed the pressure, in order to secure stability. For determining this equality, several different principles have been employed, approaching more or less to perfect accuracy, as may be seen in my Course of Mathematics, vol. 2, pa. 196, and vol. 3, pa. 256; where a popular and mechanical theory is delivered, for pretty compact or firm earth, different from former ones, and accompanied with several practical examples, which may be usefully consulted on any real occasion. Below is also inserted another new theory, for the pressure or push of semifluid and cohesive earth, communicated by a learned friend, Dr. Young, Foreign Secr. to the Royal Society.

An Essay on the Pressure of semifluid and cohesive Substances.

The resistance opposed by friction, or adhesion, to the relative motion of any two given solid or semifluid substances, is nearly proportional to the force urging the surfaces into contact. Since, however, this force must necessarily be augmented by the force of direct cohesion, which is proportional to the extent of the surfaces in contact, it follows, that a portion of the resistance to lateral motion, must also, in cohesive substances, be proportional to the magnitude of the surfaces concerned, and independent of the direct pressure. The proportion of the variable resistance, to the force on which it depends, is that of the height to the horizontal extent of an inclined plane, on which the surfaces would begin to slide on each other, if this resistance only were concerned, or if the force or weight were very great, and the extent of the surface very small: and the angle formed by such a plane, with the horizon, is called the angle of repose of the substance. The mutual cohesion of two substances, may be estimated from the thickness of a coat of one of the substances, which would be supported by it in contact with a vertical surface of the other; and both these properties may be practically determined, with respect to any internal surfaces or sections of a given substance, by raising a portion of it, terminated by a horizontal and a vertical surface, until the angle breaks off, observing both the depth and the breadth of the portion thus separating.

A. It is first required to determine the angle of fracture for a semifluid and cohesive substance, terminated by a horizontal and a vertical surface, and supported only by a horizontal force.

We have here a wedge of the given substance, tending to slide down an inclined plane, and to overcome at once the horizontal pressure, and the resistances in the direction of the plane derived from the cohesion, and from the friction produced by the sum of the other forces; and we are to determine the breadth x of that wedge, in which this tendency will be the greatest, its depth being a.

Now the weight of the wedge being expressed by $\frac{1}{2}ax$, its immediate tendency to descend along the inclined plane will be $\frac{1}{2}ax . \frac{a}{\sqrt{(aa + xx)}}$, which will be opposed by the horizontal force f, acting in a contrary direction, and reduced to $f \frac{x}{\sqrt{(aa + xx)}}$, and by the resistance derived from three sources: the first from the cohesion, which is expressed by $b\sqrt{(aa + xx)}$, b being the thickness supported by the lateral adhesion of a vertical surface; the second and third from the two pressures, represented by $\frac{1}{2}tax . \frac{x}{\sqrt{(aa + xx)}}$ and $tf. \frac{a}{\sqrt{(aa + xx)}}$, where t is the tangent of the angle of repose, the resistance being to the direct or perpendicular pressure as t to 1. Hence, for the state of equilibrium, we have the equation $\frac{1}{2}ax . \frac{a}{\sqrt{(aa + xx)}} = f. \frac{x}{\sqrt{(aa + xx)}} + b\sqrt{(aa + xx)} + \frac{1}{2}tax. \frac{x}{\sqrt{(aa + xx)}} + tf. \frac{a}{\sqrt{(aa + xx)}}$, and $\frac{1}{2}a^2x = fx + b(a^2 + x^2) + \frac{1}{2}atx^2 + atf$; whence $f = \frac{\frac{1}{2}aax - aab - bxx - \frac{1}{2}atxx}{x + at}$. This force must be a maximum in the section affording the greatest pressure, and its fluxion must vanish; whence we have $(\frac{1}{2}a^2 - 2bx - atx).(x + at) = \frac{1}{2}a^2x - a^2b - bx^2 - \frac{1}{2}atx^2$; $(b + \frac{1}{2}at)x^2 + (2abt + a^2t^2)x = a^2b + \frac{1}{2}a^3t$; $x^2 + 2atx = a^2$, $x = \sqrt{(a^2 + a^2t^2)} - at$; and if $b = 0, f = a^2[\frac{1}{2} + t^2 - t\sqrt{(1 + t^2)}]$. Hence it appears that, as Mr. Prony has already observed, the angle formed by the surface thus determined, with the vertical surface, is half the complement of the angle of repose, since $\sqrt{(1 + t^2)} - t$ is the tangent of half the angle of which the cotangent is t, as is easily shown by a trigonometrical calculation; and that this angle is independent of the magnitude of the cohesive resistance, and determined only by the friction; at the same time, if the friction vanishes, and the cohesion alone remains, we have $x = a$, the angle being 45°.

B. The portion of a semifluid and cohesive substance, of which the surfaces are horizontal and vertical, affording the greatest lateral pressure, is terminated by a plane.

For if we conceive the substance to be divided by a second vertical surface, parallel to the first, the angular situation of the upper part of the oblique termination, cut off by this surface, will obviously be correctly determined, if considered as a plane, according to the principles already laid down; and if any curved surface would afford a greater lateral pressure than a plane, the direction of the lower part of the oblique termination, considered also as a plane, would require to be different from that of the upper, and this difference might be exhibited by supposing its horizontal extent to be varied, that of the upper portion remaining the same. But in fact, the determination of the direction for this part, thus considered, will be precisely the same as for the upper part; since the proportion of the resistance to the pressure remains the same, and the horizontal force acts on the lower part of the oblique surface with the same increased intensity as the weight, the one depending on the other; so that the relations of all the forces concerned in the determination remain unaltered.

C. To determine what portion of a soft and adhesive substance, having a horizontal and a vertical surface, will stand alone.

Put $f = 0$, then $\frac{1}{2}a^2x - a^2b - bxx - \frac{1}{2}atxx = 0$; and if t is given, let $\sqrt{(1 + t^2)} - t$ be r, and $x = ra$, then $\frac{1}{2}ra^2 - a^2b - r^2a^2b - \frac{1}{2}r^2ta^3 = 0$, and $\frac{1}{2}ra - b - r^2b - \frac{1}{2}r^2at = 0$, and $a = \frac{2b + 2rrb}{r - rrt} = \frac{2b}{r} . \frac{1 + rr}{1 - rt} = \frac{4b}{r}$, and $b = \frac{1}{4}ar$; but if we observe a and x, we find $t = \frac{aa - xx}{2ax}$, and $b = \frac{aax - a^2xx}{2aa + 2xx}$. When t vanishes, x becomes equal to a, and $b = \frac{1}{4}a$: if $t = 1$, $b = \cdot1036a$, if $t = \frac{1}{2}$, $b = \cdot155a$.

D. When the surface of a soft, or semifluid and cohesive substance, is inclined to the horizon, the portion affording the greatest horizontal pressure is generally terminated by a curve.

We may suppose the substance to be divided into ver-

tical strata; and the mean depth of any stratum being called y, and the difference of the depths of its two surfaces c, we must inquire what must be its thickness x, in order to afford the greatest horizontal thrust. The weight of the stratum will then be represented by yx; and if the tangent of the elevation of the exposed surface, ascending from its angular end, be u, the length of the oblique termination of the stratum will be $\surd(x^2 + (c + ux)^2) = z$: we have then, for the state of equilibrium, the equation $yx \cdot \frac{c + ux}{z} = f \cdot \frac{x}{z} + bz + tyx \cdot \frac{x}{z} + tf \cdot \frac{c + ux}{z}$, and $f = \frac{cyx + uyxx - bzz - tyxx}{x + ct + tux} = \frac{cyx + uyxx - bxx - bcc - 2bcux - buuxx - tyxx}{x + ct + tux}$; then putting the fluxion of $f = 0$, x only being variable, we obtain $(cy + 2uyx - 2bx - 2bcu - 2bu^2x - 2tyx) \cdot (x + ct + tux) = (1 + tu) \cdot (cyx + uyx^2 - bx^2 - bc^2 - 2bcux - bu^2x^2 - tyx^2)$; $(2uy - 2b - 2bu^2 - 2ty)x \cdot (1 + tu)x + (2uy - 2b - 2bu^2 - 2ty)x \cdot ct + (cy - 2bcu) \cdot (1 + tu)x + (cy - 2bcu) \cdot ct = (1 + tu) \cdot (uy - b - bu^2 - ty)x^2 + (1 + tu) \cdot (cy - 2bcu)x - (1 + tu) \cdot bc^2$; and $x^2 + \frac{2ct}{1 + tu} \cdot x = \frac{(2bcu - cy) \cdot ct - (1 + tu) \cdot bcc}{(uy - b - buu - ty) \cdot (1 + tu)}$, whence $\frac{x}{c}$ is found $= \surd\left(\frac{tt}{(1 + tu)^2} + \frac{btu - ty - b}{(uy - b - buu - ty) \cdot (1 + tu)}\right) - \frac{t}{1 + tu}$. Having thus obtained the angular direction of the termination of the vertical stratum, which affords the greatest lateral thrust when the height is y, we may proceed to find what must be the magnitude of y for different strata, in order that they may all possess this property, and that the whole horizontal force may consequently be the greatest possible. For this purpose we must substitute $\frac{\dot{x}}{-\dot{y}}$ for $\frac{x}{c}$, x being now considered as the whole horizontal thickness, and y the whole vertical ordinate or depth, as before. Hence $-\dot{x} = \frac{\dot{y}}{1 + tu}\left(\surd\left(t^2 + \frac{(1 + tu) \cdot (btu - ty - b)}{uy - b - buu - ty}\right) - t\right) = \frac{\dot{y}}{1 + tu}\left(\surd\frac{-ty - b - btt - t^2y}{uy - b - buu - ty} - t\right) = \frac{\dot{y}}{1 + tu} \times \left(\surd\frac{b + btt + (t + t^2)y}{b + buu + (t - u)y} - t\right)$. Call $\surd(b + buu + (t - u)y)$, v, then $y = \frac{v^2 - b - buu}{t - u}$, $\dot{y} = \frac{2v\dot{v}}{t - u}$, and $-\dot{x} = \frac{2v\dot{v}}{(1 + tu) \cdot (t - u)}\surd\left(b + btt + \frac{(t + t^2)v^2 - b - buu}{t - u}\right) : v - \frac{t\dot{y}}{1 + tu} = \frac{2\dot{v}}{(1 + tu) \cdot (t - u)}\surd(b + btt - (b + buu) : (t - u) + (t + t^2) : (t - u) \cdot v^2 - \frac{t\dot{y}}{1 + tu}$: and if we call $\frac{(t - u)b + btt - (b + buu)}{t + t^2}$, d^2, we have $-\dot{x} = \frac{2\dot{v}}{(1 + tu) \cdot (t - u)}\surd\frac{1 + t^2}{t - u}\surd(d^2 + v^2) - \frac{t\dot{y}}{1 + tu}$.
But it is well known that the fluent of $\surd(a^2 + x^2)\dot{x}$ is $\frac{1}{2}x\surd(a^2 + x^2) + \frac{1}{2}a^2 \cdot \text{HL}(x + \surd(a^2 + x^2))$, and by comparison with this fluent, we obtain the equation $e - x = \frac{1}{(1 + tu) \cdot (t - u)}\surd\frac{1 + t^2}{t - u}(v\surd(d^2 + v^2) + d^2\text{HL}(v + \surd(d^2 + v^2))) - \frac{ty}{1 + tu} + e$. When, however, $t - u$ is negative, that is, when the elevation of the inclined surface is greater than could exist without the cohesion, the fluent assumes a different form, and we must make $d^2 = \frac{(u - t) \cdot (b + tt) + b + buu}{t + t^2}$; then $-\dot{x} = \frac{-2\dot{v}}{(1 + tu) \cdot (u - t)}\surd\frac{t + t^2}{u - t}\surd(d^2 - v^2) - \frac{t\dot{y}}{1 + tu}$. But it is known that the fluent of $\surd(a^2 - x^2)\dot{x}$ is $\frac{1}{2}x\surd(a^2 - x^2) + \frac{1}{2}a^2$ arc sine $\frac{x}{a}$; hence $e - x$ becomes $= e - \frac{1}{(1 + tu) \cdot (u - t)}\surd\frac{t + t^2}{u - t}(d\surd(d^2 - v^2) + d^2 \text{ arc sine } \frac{v}{d}) - \frac{ty}{1 + tu}$.

E. When the variable resistance vanishes, the curve becomes a parabola.

For if $t = 0$, $\frac{x}{c}$ or $\frac{\dot{x}}{-\dot{y}}$, becomes $= \surd\frac{b}{b + buu - uy}$, whence $x + e = \frac{2}{u}\surd(b^2 + b^2u^2 - buy)$; but when $x = 0$, $y = a$, and $e = \frac{2}{u}\surd(b^2 + b^2uu - bau)$, $(x + \frac{2}{u}\surd(b^2 + b^2uu - bau))^2 = \frac{4bb}{uu} + 4b^2 - \frac{4b}{u}y = x^2 + \frac{4bb}{uu} + 4b^2 - \frac{4ba}{u} + \frac{4x}{u}\surd(b^2 + b^2uu - bau)$, and $y = a - \surd(1 + uu - \frac{a}{b}u)x - \frac{u}{4b}x^2$. In order to determine the whole horizontal force, we must find its fluxion by substituting $\dot{x}$ for x, and $-\dot{y}$ for c, in the equation for f, which becomes $-y\dot{y} + uy\dot{x} - b\dot{x} - b\frac{\dot{y}\dot{y}}{\dot{x}} + 2bu\dot{y} - bu^2\dot{x}$; and since $-\dot{y} = \surd(1 + uu - \frac{a}{b}u)\dot{x} + \frac{u}{2b}x\dot{x}$, we obtain the fluent $= g - \frac{1}{2}y^2 + aux - \frac{u}{2}\surd(1 + uu - \frac{a}{b}u)x^2 - \frac{uu}{12b}x^3 - bx - bx - bu^2x + aux - \frac{u^2}{12b}x^3 - \frac{u}{2}\surd(1 + uu - \frac{a}{b}u)x^2 + 2buy - bu^2x = g + (2au - 2b - 2bu^2)x - u\surd(1 + u^2 - \frac{a}{b}u)x^2 - \frac{uu}{6b}x^3 + 2buy - \frac{1}{2}y^2$, which must vanish when $x = 0$, and $y = a$, or $g + 2bau - \frac{1}{2}a^2 = 0$, and $g = \frac{1}{2}a^2 - 2bau$. When $y = 0$, $x + e = \frac{2b}{u}\surd(1 + u^2)$, and $x = \frac{2b}{u}\surd(1 + u^2) - \frac{2b}{u}\surd(1 + u^2 - \frac{a}{b}u)$, and the whole force is $\frac{1}{2}a^2 - 2bau + (2au - 2b - 2bu^2)x - u\surd(1 + u^2 - \frac{a}{b}u)x^2 - \frac{uu}{6b}x^3$.

Here it must be observed, that when $\frac{a}{b}u$ is equal to or greater than $1 + u^2$, the problem becomes impossible, the value of $\frac{x}{c}$ becoming first infinite, and then imaginary. We may take for an example the case $u = \frac{1}{10}$ and $a = 10b$, then $x = 2a(\surd 1{\cdot}01 - {\cdot}1) = 1{\cdot}81a$, and the whole force is $\frac{1}{2}a^2 - {\cdot}02a^2 + ({\cdot}2a - {\cdot}2a - {\cdot}002a)x - {\cdot}01x^2 - \frac{x^3}{60a} = {\cdot}345a^2$. If $u = 1$, and $a = 2b$, $x = \surd 2a$, and the force $\frac{1}{2}a^2 - a^2 - \surd 2a^2 - \frac{2}{3}\surd 2a^2$, which, being negative, implies that there can be no separation. In order to show how little the force thus determined differs from that which is afforded by a section terminated by a plane surface, even where the variable resistance is supposed to be absent, we may calculate, for the depth of a, the horizontal extent x of a prismatic section affording the greatest pressure, the equation of the forces will then be $\frac{1}{2}ax\,\frac{a+ux}{z} - bz = f\,.\,\frac{x}{z}$, and $f = \frac{1}{2}a^2 + \frac{1}{2}aux - \frac{bz^2}{x} = \frac{1}{2}a^2 + \frac{1}{2}aux - bx - \frac{ba^2}{x} - 2bau - bu^2x$, and when its fluxion vanishes, $\frac{1}{2}au - b + \frac{ba a}{xx} - bu^2 = 0$, consequently $\frac{aa}{xx} = 1 + u^2 - \frac{au}{2b}$, which, when $u = \frac{1}{10}$ and $a = 10b$, becomes ·51, and $x = 1{\cdot}4a$, whence f is found $\cdot 337a^2$, which is not one-fortieth part less than the more correct result of the former calculation. When the cohesion vanishes, and the variable resistance alone remains, the maximum of force seems in all cases to be afforded by a plane surface, whether the resistance is horizontal or not.

F. It remains to be determined, what is the proportion of the forces, when the pressure, instead of being horizontal, is supposed to be oblique, as will be the case when the surface of a wall is opposed to the thrust of earth, and exhibits a lateral adhesion or friction, as well as a direct resistance.

We have here two new forces to be considered, the one constant, representing the adhesion of the wall, the other depending on f the horizontal pressure, both tending directly to lessen the weight, if we consider the surface of the wall as vertical. We may still call the horizontal extent of the prismatic portion x, disregarding the slight inaccuracy of supposing the oblique surface a plane; and u being, as above, the tangent of the elevation of the exposed surface, the friction of the wall being, for the sake of simplicity, considered as equal to the internal friction of the materials, which it can never exceed, and of which it will seldom fall short, we have the equation $(\frac{1}{2}ax - ab - tf)\,\frac{a+ux}{z} - bz - t(\frac{1}{2}ax - ab - tf)\,\frac{x}{z} - tf\,\frac{a+ux}{z} = f\frac{x}{z}$, and $f = \frac{(\frac{1}{2}ax - ab).(a+ux) - bz^2 - tx(\frac{1}{2}ax - ab)}{t(a+ux) - ttx + t(a+ux) + x}$; and when its fluxion vanishes, $(\frac{1}{2}a^2 + aux - abu - 2bx - 2abu - 2bu^2x - atx + tab).(2t(a+ux) - t^2x + x) = (2tu - t^2 + 1).[(\frac{1}{2}ax - ab).(a+ux) - bx^2 - b(a+ux)^2) - \frac{1}{2}tax^2 + tabx]$, or $[(au - 2b - 2bu^2 - at)x + \frac{1}{2}a^2 - 3abu + atb].[(2tu - t^2 + 1)x + 2at] = (2tu - t^2 + 1).[(\frac{1}{2}au - b - bu^2 - \frac{1}{2}at)x^2 + (\frac{1}{2}au - abu - 2abu + atb)x - 2a^2b]$; whence $x^2 + \frac{4atx}{2tu - tt + 1} + \frac{2at(\frac{1}{2}a^2 - 3abu + atb)}{(au - 2b - 2buu - at).(2tu - tt + 1)} = \frac{1}{2}x^2 - \frac{2a^2b}{au - 2b - 2buu - at}$, or $x^2 + \frac{4atx}{2tu - tt + 1} = 2a^2.\frac{2btu - at - 2b}{(2tu - tt + 1).(au - 2b - 2buu - at)}$, and x may be found by completing the square.

But for practical use on a large scale, we may neglect the cohesive resistance without impropriety, its value being generally variable, from the effects of moisture and agitation, so that it would be unsafe to place any dependence on it, even if it were much larger than commonly happens: we may therefore make $b = 0$, and $x^2 + \frac{4atx}{2tu - tt + 1} = 2a^2\frac{t}{(2tu - tt + 1).(t - u)}$, and $x + \frac{2at}{2tu - tt + 1} = \pm a\sqrt{(\frac{4t^2}{(2tu - tt + 1)^2} + \frac{2t}{(2tu - tt + 1).(t - u)})} = \pm\frac{a}{2tu - tt + 1}\sqrt{\frac{2t + 2t^3}{t - u}}$; whence f may be readily determined, being equal to $\frac{1}{2}ax.\frac{a - (t - u)x}{2at + 2tux - ttx + x}$.

If the wall, instead of being vertical, be inclined towards the bank, which is a condition highly favourable to its stability, the oblique direction of the thrust must also be taken into consideration, in computing its magnitude. Let u be now the tangent of the deviation of the wall from the vertical direction, the surface of the earth being horizontal, and let x be, as above, the whole horizontal extent of the portion affording the greatest thrust, the force f being perpendicular to the wall. We shall then have for the weight, $\frac{1}{2}a(x - au)$, acting in the direction of the oblique surface z with the force $\frac{1}{2}a(x - au)\frac{a}{z}$, and causing a resistance $\frac{1}{2}at(x - au)\frac{x}{z}$. In order to reduce the force f to the same direction, we must find the sine and cosine of the angle contained by the oblique surface z and the wall, which are $\frac{x - au}{\sqrt{(1 + uu)}}$, and $\sqrt{(1 - \frac{(x - au)^2}{z^2 + u^2z^2})} = \frac{1}{z}\sqrt{(a^2 + x^2\frac{(x - au)^2}{1 + u^2})} = \frac{a + ux}{z\sqrt{(1 + uu)}}$; whence we have $f\frac{x - au}{z\sqrt{(1 + uu)}}$, and $tf\frac{a + ux}{z\sqrt{(1 + uu)}}$; and the friction of the wall, ft, being reduced in a similar manner, gives $ft\frac{a + ux}{z\sqrt{(1 + uu)}}$, and $-ft^2\frac{x - au}{z\sqrt{(1 + uu)}}$, whence we have the equation $\frac{1}{2}a(x - au).\frac{a}{z} = \frac{1}{2}at(x - au)\frac{x}{z} + f\frac{x - au}{z\sqrt{(1 + uu)}} + ft\frac{a + ux}{z\sqrt{(1 + uu)}} + ft\frac{a + ux}{z\sqrt{(1 + uu)}} - ft^2\frac{x - au}{z\sqrt{(1 + uu)}}$, or $a^2(x - au) = atx(x - au) + 2f\frac{x - au}{\sqrt{(1 + uu)}} + 4ft\frac{(a + ux)}{\sqrt{(1 + uu)}} - 2ft^2\frac{x - au}{\sqrt{(1 + uu)}}$; consequently $\frac{f}{a\sqrt{(1 + uu)}} = \frac{(a - tx).(x - au)}{(2 - 2tt).(x - au) + 4t(a + ux)}$: this we may call $\frac{b + cx + dxx}{ex + g}$; and when its fluxion vanishes, $(c + 2dx).(ex + g) = eb + cex + dex^2 = cex + 2dex^2 + cg + 2dgx$, $x^2 + \frac{2g}{e}x = \frac{b}{d} - \frac{cg}{de}$, and $x = \sqrt{(\frac{b}{d} - \frac{cg}{de} + \frac{gg}{ee})} - \frac{g}{e}$. Here $b = -a^2u$, $c = a + atu$, $d = -t$, $\frac{b}{d} = \frac{au}{t}$, $\frac{c}{d} = -\frac{a}{t} - au$, $e = 2 - 2t^2 + 4tu$, and $g = 4at - (2 - 2tt)\,au$.

G. It will now be easy to find the dimensions of a wall, capable of withstanding the thrust of a given bank of earth, without being overturned or carried away horizontally, provided that we know the elevation at which the surface of the earth is capable of supporting itself.

It is obvious that the whole pressure, like that of fluids, must be proportional to the square of the depth a, neglecting the effect of adhesion; and consequently that the centre of pressure must be at one-third of the height. We may consider the specific gravity of the wall as equal to that of the earth, which will in general allow us some excess of stability for the security of the work: then if the wall be vertical, and its thickness be y, the force being referred to the outside of the base of the wall as the fulcrum of a lever, we must have, in order that it may not be overturned, $\frac{1}{3}af = tfy + \frac{1}{2}ayy$, and $y^2 + \frac{2ft}{a}y = \frac{2}{3}f$, $y = \sqrt{(\frac{2}{3}f + \frac{f^2t^2}{a^2})} - \frac{ft}{a}$. And in the same manner, if we suppose the section of the wall to be triangular, its outer surface being sloped off, we have $\frac{1}{3}af = tfz + \frac{1}{2}azz$, and $z = \sqrt{(\frac{4}{3}f + (\frac{4f^2t^2}{a^2})} - \frac{2ft}{a}$, z being the thickness at the bottom. When the wall is inclined towards the bank, in an angle of which the tangent is u, f being the force perpendicular to it, and y the horizontal thickness of the wall, the force f will act on a lever of which the length is $\frac{1}{3}a\sqrt{(1+uu)} + \frac{uy}{\sqrt{(1+uu)}}$, and the friction tf will act at the distance $\frac{y}{\sqrt{(1+uu)}}$, and the weight at $\frac{1}{2}y + \frac{1}{2}au$, whence $\frac{1}{3}af\sqrt{(1+uu)} + \frac{fuy}{\sqrt{(1+uu)}} = \frac{fty}{\sqrt{(1+uu)}} + \frac{1}{2}ay^2 + \frac{1}{2}a^2uy$, and $y^2 + (\frac{2ft-2fu}{a\sqrt{(1+uu)}} + au)y = \frac{2}{3}f\sqrt{(1+uu)}$; consequently $y = \sqrt{[\frac{2}{3}f\sqrt{(1+uu)} + (\frac{ft-fu}{a\sqrt{(1+uu)}} + \frac{1}{2}au)^2]} - \frac{ft-fu}{a\sqrt{(1+uu)}} - \frac{1}{2}au$.

If the wall be not securely fixed at its foundations, for example when the earth is dug away beyond it, it may be liable to slide away laterally more easily than to be overturned. Supposing it simply to rest on materials similar to those which constitute the bank, we may calculate the thickness sufficient to produce a resistance equivalent to the thrust; thus if the wall is vertical, we must have $f = t(ay + ft)$, and $ay = \frac{f}{t} - ft$; but when the wall is inclined, the force f takes from the weight the portion $f\frac{u}{\sqrt{(1+uu)}}$, and the friction adds to it only $ft\frac{1}{\sqrt{(1+uu)}}$, the horizontal thrust being $f\frac{1}{\sqrt{(1+uu)}}$; whence $f\frac{1}{\sqrt{(1+uu)}} = t(ay - f\frac{u}{\sqrt{(1+uu)}} + f\frac{t}{\sqrt{(1+uu)}}$, and $ay = \frac{f}{\sqrt{(1+uu)}}(\frac{1}{t} + u - t)$.

II. In the case of driving a pile, the pressure of the soft materials is modified by the inversion of the direction of the friction of the vertical surface, which now acts in conjunction with the weight of the materials, so that $\frac{1}{2}ax - ab - tf$ becomes $\frac{1}{2}ax + ab + tf$, or, if $b = 0$, simply $\frac{1}{2}ax + tf$; and $f = \frac{1}{2} \cdot \frac{aa - atx}{tt+1}$, which is greatest when x is least, and becomes ultimately $\frac{\frac{1}{2}aa}{tt+1}$, and the resistance tf will be $\frac{1}{2}a^2\frac{t}{tt+1}$, which is a maximum when $tt + 1 = 2t$, or $t = 1$, being then $\frac{1}{4}a^2$; and in this case the resistance derived from the friction, on the whole of the lateral surfaces of a square pile, would be equal to the weight of the earth which would press on one of the surfaces, if it were buried at the depth to which its lower end has penetrated. There would however be other resistances from the tenacity preventing the ready separation of the earth before the pile, which would perhaps considerably exceed the friction thus determined.

I. Such of the results of these calculations, as are most likely to be of practical utility, may be conveniently exhibited in the form of a table: but it must be remembered, in its application, that some additional strength ought always to be given to the works concerned, in order to insure their stability, and that occasional agitation will very much diminish the resistance of almost all kinds of materials; to say nothing of the precaution necessary to obviate the effects of the penetration of water; which will not only act by its own hydrostatic pressure, but also weaken the adhesion of the earth employed, unless a sufficient number of apertures can be provided for allowing it to escape.

An instance has occurred on a large scale, where the wall of a dock has given way horizontally, when its mean thickness was about ·230, the ground having been dug away beyond its foundation: it was of brick, and somewhat curved, being vertical at the top, while the inclination of the chord, or the mean inclination, was 11° 18′, as is supposed in the second table. Hence it appears that the friction must have been somewhat less than ½ of the weight, and that the materials would have stood at an angle of about 25°: to have overturned this wall, the materials must have exhibited a friction of about one-third of the weight, and have been incapable of standing at a greater inclination than about 20°.

In general, it will be unquestionably proper to calculate on a friction not exceeding ½ of the weight, and to make the thickness of a wall, if vertical, at least $\frac{1}{10}$ or perhaps $\frac{1}{3}$ of its height, and if inclined in an angle of 10° or 12°, about $\frac{1}{5}$, taking care to secure the foundation from sliding, to which an inclined wall will otherwise be liable if its thickness be less than $\frac{1}{4}$, though a vertical wall would be safe in this respect if its thickness were sufficient to secure it from being overturned. The disposal of a part of the materials of the wall in the form of counterforts, or buttresses, will add to the strength in either case, especially with respect to the danger of overturning: the curvature, which is a considerable convenience in the case of a dock, tends in a slight degree to lessen the stability with respect to sliding, and makes it still more necessary to attend to the security of the foundation. On the other hand, when we have an opportunity of ascertaining, by a simple experiment, the utmost fluidity that can be communicated by accidental moisture to a chalky or gravelly soil, these calculations may often justify us in saving a very great expense, by proportioning the strength of the works to the object required to be attained by them.

Centre of PRESSURE, in Hydrostatics, is that point of any plane, to which, if the total pressure were applied, its effect upon the plane would be the same as when it was distributed unequally over the whole; or it is that point in which the whole pressure may be conceived to be united; or it is that point to which, if a force were applied equal to the total pressure, but with an opposite direction, it would exactly balance, or restrain the effect of the pressure, so that the body pressed on would not incline to either side. Thus, if ABCD (2d fig. above) be a vessel of water, and the side BC be pressed upon with a force equivalent to 20 pounds of water, this force is unequally distributed over BC, for the parts near B are less pressed than those near C, which are at a greater depth; and therefore the efforts of all the particular pressures are united in some point E, which is nearer to C than to B; and that point E is called the centre of pressure: and if to that point a force equivalent to 20 pounds weight be applied, it will affect the plane BC in the same manner as by the pressure of the water distributed unequally over the whole; and if to the same point the same force be applied in a contrary direction to that of the pressure of the water, the force and the pressure will balance each other, and by opposite endeavours destroy each other's effects. Supposing a cord EFG fixed at E, and passing over the pulley F, has a weight of 20 pounds annexed to it, and that the part of the cord FE is perpendicular to BC; then the effort of the weight G is equal, and its direction contrary, to that of the pressure of the water. Now if E be the centre of pressure, these two powers will be in equilibrio, and mutually destroy each other's effects.

This point E, or the centre of pressure, is the same with the centre of percussion of the plane BC, the point of suspension being B, the surface of the water. And if the plane be oblique, the case is still the same, taking for the axis of suspension, the intersection of that plane and the surface of the fluid, both produced if necessary. See Cotes's Lectures, pa. 40, &c.—The centre of pressure upon a plane parallel to the horizon, or upon any plane where the pressure is uniform, is the same as the centre of gravity of that plane. For the pressure acts upon every part in the same manner as gravity does.

PRESTET (JOHN), a priest of the Oratory, was born at Chalons-sur-Saone, in 1658. He went to Paris early in life, where, having finished his studies, he was entertained by father Malbranche, who taught him mathematics, in which his young pupil made so rapid a progress, that at 17 years of age he published the first edition of his Elemens des Mathematiques. In the same year he entered the congregation of the Oratory, and taught mathematics with much reputation, particularly at Angers and at Nantes. But he died in 1690, at 32 years of age.—His Elemens, above noticed, contain many curious problems: the best edition is that of 1689, in 2 vols. 4to.

PRICE (RICHARD), D. D. and F. R. S. was born in Glamorganshire in 1723, and died in 1791, about 68 years of age. He received his education in a private academy, after which he became minister to a congregation at Newington, in Middlesex; whence he removed to that of Hackney. He was also lecturer of the meeting-house in the Old Jewry, in London. In 1764 he became F. R. S. and D. D. by a diploma from a Scotch university. At the time of the American war he made himself conspicuous by his zeal in the cause of liberty, which he also displayed on several other occasions: and for the publication of his Observations on Liberty and Civil Government, he had the thanks of the city of London. Among many other learned accomplishments, Dr. Price was no mean mathematician, which enabled him to treat with peculiar precision, the calculations relating to political arithmetic, population, annuities, &c. It is even said that he had the honour of suggesting to the late prime minister, Mr. Pitt, the measure of the present sinking fund, to extinguish the national debt, by the allotment of an annual million to accumulate at compound interest. Dr. Price's principal works are: 1. Four Dissertations on Providence and Prayer; on the Importance of Christianity, &c. 2. A Review of the principal Questions and Difficulties in Morals. 3. Observations on Reversionary Payments, Annuities, &c, 2 vols. 8vo. 4. Discussion of the Doctrines of Materialism and Necessity, in a correspondence with Dr. Priestley. 5. Essay on the Population of England and Wales. 6. A volume of Sermons.

PRIESTLEY (JOSEPH), L L. D. and F. R. S. was born on March 13, 1733, at Field-head, in the parish of Birstall, in the west-riding of Yorkshire. His father was concerned in the cloth manufacture, and intended his son Joseph also for trade, but was induced to change his mind by the youth's early attachment to reading and literary pursuits. After a pretty extensive course of classical studies, at 19 years of age he entered, as a divinity student, the academy of Daventry, under Dr. Ashworth, as successor of that kept by Dr. Doddridge at Northampton. He then officiated for some years as a minister at different places: and in 1761 joined the academy of Warrington, as a lecturer in belles lettres; where his Biographical and Historical Charts appeared, as also his writings on subjects of history, general politics, &c: and here, in 1767, was published his History of Electricity. In 1770, Dr. Priestley accepted the situation of domestic librarian to the earl of Shelburne, or rather his literary and philosophical companion, in the hours that could be devoted to such pursuits. His "History and Present State of Discoveries relating to Vision, Light, and Colours," in 2 vols. 4to, appeared in 1772; which may be considered as a 2d part of a general history of the philosophical sciences; and which indeed proved the last, as the encouragement of this work fell far short of that of the History of Electricity. In 1775 came out his "Examination of Dr. Reid on the Human Mind; Dr. Beattie on the Nature and Immutability of Truth; and Dr. Oswald's Appeal to Common Sense." In 1777, "Disquisitions relating to Matter and Spirit." And soon after, his correspondence with Dr. Price, relative to the same points. In several volumes of the Philos. Trans., as well as in separate publications of his own, are seen his numerous papers on discoveries relating to aëriform fluids, and other chemical subjects; besides many others on theology.

Dr. Priestley's engagement with lord Shelburne having ceased in 1780, he accepted the office of pastor to a congregation at Birmingham; whence soon after issued some of the most important of his theological works; from which arose several controversies on such topics, with Dr. Horsley and other learned men. Dr. Priestley remained at Birmingham till 1791, when his house and library were burnt, with many others, in a popular commotion in that place. After some little time an invitation to succeed Dr. Price, in a congregation at Hackney, gave him a temporary residence; till, in 1794, he sailed for North America, where he settled at the town of Northumberland, in the state of Pennsylvania, for the remainder of his life; and where he died the 9th of February 1804, at nearly 71 years of age.

The following has been given as a true character of Dr. Priestley.—"I beg you will insert the following faithful portrait of a man whose character has been grossly misrepresented by interested enemies, and misconceived by a deluded public.—He was a patient, indefatigable, acute, and judicious experimental philosopher; a candid, bold, and unguarded disputant in theology; a sincere and zealous Christian, a serious and rational preacher of the practical morality of religion—but without the least pretension to, or affectation of, oratorical ornaments. His mind embraced the whole extent of the knowledge and literature in his closet: but in the affairs of the world, he was a plain, uninformed, unaccomplished, honest man. What he believed to be true he thought it his duty to propagate, without any regard to his own interest or the prejudices of mankind; but being overpowered by calumny and oppression, he was compelled to seek a residence among strangers, and leave his principles and character to the impartial judgment of posterity."

PRIMARY *Planets*, are those which revolve round the sun as a centre. Such are the planets Mercury, Venus, Terra, (the Earth,) Mars, Vesta, Juno, Pallas, Ceres, Jupiter, Saturn, and Herschel, &c. They are thus called, in contradistinction from the secondary planets, or satellites, which revolve about their respective primaries. See PLANET.

PRIME and ULTIMATE RATIOS, a method invented by sir Isaac Newton, at once to avoid the tediousness of the ancients and the inaccuracy of the moderns. The foundation of this method is contained in the first lemma of the first book of the Principia.—This lemma may be thus explained. Let there be two quantities, one fixed and the other varying, so related to each other, that, 1st, the varying quantity continually approaches to the fixed quantity; 2d, that the varying quantity never reaches or can pass beyond the fixed one; 3dly, that the varying quantity approaches nearer to the fixed one than by any assigned difference; then is such a fixed quantity called the limit of the varying one; or, in a looser way of speaking, these quantities may be said to be ultimately equal or in a ratio of equality.

On this subject, see Newton's Principia, lib. 1; Smith's Fluxions; Ludlam on Ultimate Ratios; &c.

PRIMES, denote the first divisions into which some whole or integer is divided. As, a minute, or prime minute, the 60th part of a degree; or the first place of decimals, being the 10th parts of units; or the first division of inches in duodecimals, being the 12th parts of inches; &c.

PRIME *Numbers*, are those which can only be measured by unity, or exactly divided without a remainder, 1 being the only aliquot part: as 2, 3, 5, 7, 11, 13, 17, &c. And they are otherwise called Simple or Incomposite numbers.

The peculiar property of prime numbers, as to their forms, the method of finding them, and the many collateral truths that have been derived from the investigations of those properties, have rendered them deserving of the particular attention of mathematicians; and accordingly, we find some of the most celebrated analysts of modern times have bestowed on the theory of those numbers many elaborate and ingenious investigations; among whom, those who have more particularly distinguished themselves, are Bachet, Fermat, Euler, Lagrange, Legendre, and Gauss; the united efforts of these celebrated authors to any particular subject, cannot fail of giving it considerable importance in the opinion of mathematicians, at the same time that we may expect from their combined and concentrated labours, that many interesting truths have been the reward of so much talent and ingenuity.

It would be contrary to the plan of this work to enter at any length into the investigations above alluded to, but the result of them will no doubt be acceptable to the reader; we shall therefore content ourselves with recording some of the most important of those propositions, referring for their investigations and demonstrations to the authors above quoted, viz, Bachet's Diophantus published in 1621, and his work entitled, Problems plaisans et delectables &c; Fermat's edition of Bachet's Diophantus, with notes, published in 1670; Euler's Algebra published in German 1770, and since translated into the Russian, French, and English languages, with the additions by Lagrange, on the same subject; also to the Analysis Infinitorum of the same author, and more particularly to the Petersburg Acts, which contain many of the ingenious labours of this celebrated geometer; Lagrange's additions to Euler's Algebra above quoted, and to the Berlin Memoirs from 1760 for several years. But the most elaborate and connected works on the subject of numbers are those of Legendre, entitled Essai sur la Theorie des Nombres, second edition, published in 1808; and the Disquisitiones Arithmeticæ by M. Gauss, published at Leipsick in 1801, and since (1807) translated into French by Poulet Delisle, under the title of Recherches Arithmetiques.

In these works the reader will find the subject of numbers handled in the most masterly manner, many particular properties of the prime numbers accurately demonstrated, and their applications to various parts of the Indeterminate and general Analysis.

Every prime number, greater than 2, is of one of the forms $4n + 1$, or $4n - 1$.

Every prime number, greater than 3, is of one of the forms $6n + 1$, or $6n - 1$.

And as, in the former case, n may be either even or odd; it therefore follows, that every prime number, except 2, is of one of the forms $8n + 1$, $8n + 3$, $8n + 5$, or $8n + 7$.

In the same manner we may divide prime numbers into classes according to any modulus at pleasure, but the last four forms, in which are included the first two forms $4n + 1$ and $4n - 1$, are those which are found to possess the most distinct properties.

But though every prime number, except 2, is contained in one or other of these four forms, the converse of the proposition is not true, namely, that every number in those forms is a prime number. Indeed no formula has yet been discovered that belongs exclusively to prime numbers, nor has any direct rule been given for finding them, or for ascertaining whether a given number be prime or not; Euler has however considerably simplified the method of trials, in this latter case, by means of the different forms of divisors that belong to certain algebraical formulæ; thus, he has shown, in the Berlin Memoirs for 1772, that $A = 2^{31} - 1$ can have no divisors except numbers of the form $248n + 1$, or $248n + 63$; and having made trials of all the prime numbers in those forms, less than 46339, the root of the number A, and finding that none of them divided A, he thence confidently concludes that $2^{31} - 1 = 2147483647$ is a prime number: and this is the greatest of those that have been verified at present.

It is needless to observe, that without some method similar to the one above given, we should have no means of ascertaining whether the number was prime or not, but by trying every prime number for a divisor from 1 to $\sqrt{A}$, that is, from 1 to 46339, which would be too laborious a task for any one to have attempted.

Fermat had asserted that both $2^{31} - 1$ and $2^{32} - 1$ were prime numbers, but Euler has shown that this last may be decomposed into the factors $3 \cdot 5 \cdot 17 \cdot 257 \cdot 65537$.

Eratosthenes invented a method of finding those numbers, but it is rather mechanical than analytical; this is generally spoken of under the appellation of Eratosthenes' Sieve, or the Sieve of Eratosthenes, a description of which is given under that article. See SIEVE.

Properties of Prime Numbers.

Every prime number, $4n + 1$, is the sum of two squares, or is of the form $x^2 + y^2$. Thus $17 = 4^2 + 1^2$; $29 = 5^2 + 2^2$; $37 = 6^2 + 1^2$, &c.

Every prime number, $8n + 1$, is at the same time of the three forms $x^2 + y^2$, $x^2 + 2y^2$, and $x^2 - 2y^2$. Thus $41 = 5^2 + 4^2 = 3^2 + 2 \cdot 4^2 = 7^2 - 2 \cdot 2^2$.

Every prime number $8n + 3$, is of the form $x^2 + 2y^2$. Thus $43 = 5^2 + 2 \cdot 3^2$, and $59 = 3^2 + 2 \cdot 5^2$, &c.

Every prime number, $8n + 7$, is of the form $x^2 - 2y^2$. Thus $31 = 7^2 - 2 \cdot 3^2$ and $47 = 7^2 - 2 \cdot 1^2$, &c.

The demonstrations of these four theorems were first given by Lagrange, in the Berlin Memoirs for 1775; they may also be found in the notes subjoined to the second English edition of Euler's Algebra. It is likewise to Lagrange that we are indebted, if not for the demonstration of the properties contained in the following table, at least for pointing out the method that led to them, as is ingenuously acknowledged by Legendre, at pa. 286, 1st edition, and at pa. 262, 2d edition of his Theory of Numbers, whence this table is extracted.

Table of the Forms of Prime Numbers.

	Prime Numbers.	Forms.
1	$4n + 1$	$y^2 + z^2$
2	$6n + 1$	$y^2 + yz + z^2$
3	$8n + 1, 7$	$y^2 - 2z^2$
4	$8n + 1, 3$	$y^2 + 2z^2$
5	$12n + 1$	$y^2 - 3z^2$
6	$12n + 11$	$3y^2 - z^2$
7	$14n + 1, 9, 11$	$y^2 + 7z^2$
8	$20n + 1, 9, 11, 19$	$y^2 - 5z^2$
9	$20n + 1, 9$	$y^2 + 5z^2$
10	$20n + 3, 7$	$2y^2 + 2yz + 3z^2$
11	$24n + 1, 19$	$y^2 - 6z^2$
12	$24n + 5, 25$	$6y^2 - z^2$
13	$24n + 5, 11$	$2y^2 + 3z^2$
14	$24n + 1, 7$	$y^2 + 6z^2$
15	$28n + 1, 9, 25$	$y^2 - 7z^2$
16	$28n + 3, 19, 27$	$7y^2 - z^2$
17	$30n + 1, 19$	$y^2 + 15z^2$
18	$30n + 17, 23$	$3y^2 + 5z^2$
19	$40n + 1, 9, 31, 39$	$y^2 - 10z^2$
20	$40n + 3, 13, 27, 37$	$2y^2 - 5z^2$
21	$40n + 1, 9, 11, 19$	$y^2 + 10z^2$
22	$40n + 7, 13, 23, 37$	$2y^2 + 5z^2$
23	$120n + 11, 29, 59, 101$	$5y^2 + 6z^2$
24	$120n + 13, 37, 43, 67$	$10y^2 + 3z^2$
25	$120n + 1, 31, 49, 79$	$y^2 + 30z^2$
26	$120n + 17, 23, 47, 113$	$2y^2 + 15z^2$

Beside the properties of prime numbers above enumerated, and those which are given under the article NUMBER, we have another to notice, the discovery of which has been the admiration of every mathematician in Europe, namely, the solution of the equation $x^n - 1 = 0$, when n is a prime number.

The first investigation and demonstration of this problem was published by M. Gauss, in his truly ingenious work entitled Disquisitiones Arithmeticæ; though it seems that Vandermonde had asserted, in the Memoirs of the Academy of Sciences, at Paris in 1771, pa. 416, but without explaining the method, that such equations were always resolvable by means of equations of inferior degrees. It is however to M. Gauss that we are indebted for the complete development of this interesting theorem, he having shown, in the most satisfactory manner, that when n is a prime number, and $(n - 1)$ is resolved into its prime factors $a^{\alpha} b^{\beta} c^{\gamma}$ &c, that the solution of the equation $x^n - 1 = 0$ may be obtained by means of α equations of the degree a,

β of the degree b, γ of the degree c, &c; thus the equation $x^{73} - 1 = 0$, $(73 - 1$ being equal to $3^2 \cdot 2^3)$ is resolved by means of two equations of the third degree, and three of the second; and $x^{19} - 1 = 0$, (as $18 = 3^2 \cdot 2$) is resolved by means of two cubic, and one quadratic equation. And hence it follows, that when $n = 2^m + 1$ that the equation $x^n - 1 = 0$ may be resolved by means of m quadratic equations, in which case the roots may be found by construction, and consequently the circle may, with such values of n, be divided into n equal parts by means of the scale and compasses only, which was always thought to be impossible till the appearance of the work above mentioned.

Since 17 is a prime number of this form, that is, $17 = 2^4 + 1$, therefore a circle may be divided geometrically into 17 equal parts; and since $15 = 3 \times 5$, and $16 = 2^4$, therefore the circle may be divided into equal parts represented by the three consecutive numbers 15, 16 and 17; the same is also true of the three numbers 255, 256, and 257, since $255 = 3 \times 5 \times 17$; $256 = 2^8$, and $257 = 2^8 + 1$: also of the three 65535, 65536, and 65537, because $65535 = 255 \times 257$, $65536 = 2^{16}$, and $65537 = 2^{16} + 1$. But as $2^{32} + 1$ is not a prime, we cannot pursue this reasoning any farther. See Gauss's Disquisitiones Arithmeticæ, Legendre's Essai sur la Theorie des Nombres, 2d Edition, and the Complement to Lacloix's Algebra.

The following Table contains all the prime numbers, and all the odd composite numbers, under 10,000, with the least prime divisors of these; the description, nature, and use of which, see immediately following the table.

In the foregoing table, all the odd numbers that end with 5 are omitted, because it is known that 5 is a divisor, or aliquot part of every such number.—The disposition of the prime and composite odd numbers in this table, is along the top line, and down the first or left-hand column; while their least prime divisors are placed in the angles of meeting in the body of the page. Thus, the figures along the top line, viz, 0, 1, 2, 3, 4, &c, to 99, are so many hundreds; and those down the first column, from 1 to 99 also, are units or ones; and the former of these set before the latter, make up the whole number, whether it be prime or composite; just like the disposition of the natural numbers in a table of logarithms. Thus the 16 in the top line, joined with the 19 in the first column, makes the number 1619: the angle of their meeting, viz, of the column under 16, and of the line of 19, being blank, shows that the number 1619 has no aliquot part or divisor, or that it is a prime number. In like manner, all the other numbers are primes that have no figure in their angle of meeting, as the numbers 41, 401, 919, &c. But when the two parts of any number have some figure in their angle of meeting, that figure is the least divisor of the number, which is therefore not a prime, but a composite number: so 301 has 7 for its least divisor, and 803 has 11 for its least divisor, and 1633 has 23 for its least divisor.

Hence, by the foregoing table, are immediately known at sight all the prime numbers up to 10,000; and hence also are readily found all the divisors or aliquot parts of the composite numbers, namely in this manner: Find the least divisor of the given number in the table, as above; divide the given number by this divisor, and consider the quotient as another or new number, of which find the least divisor also in the table, dividing the said quotient by this last divisor; and so on, dividing always the last quotient by its least divisor found in the table, till a quotient be found that is a prime number: then are the said divisors and the last or prime quotient, all the simple or prime divisors of the first given number; and if these simple divisors be multiplied together thus, viz, every two, and every three, and every four, &c, of them together, the several products will make up the compound divisors or aliquot parts of the first given number; noting, that if the given number be an even one, divide it by 2 till an odd number come out.

For example, to find all the divisors or component factors of the number 210. This being an even number, dividing it by 2, one of its divisors, gives 105; and this ending with 5, dividing it by 5, another of its factors, gives 21; and the least divisor of 21, by the table is 3, the quotient from which is 7; therefore all the prime or simple factors of the given number, are 2, 3, 5, 7. Set these therefore down in the first line as in the margin; then multiply the 2 by the 3, and set the product 6 below the 3; next multiply the 5 by all that precede it, viz, 2, 3, 6, and set the products below the 5; lastly multiply the 7 by all the seven factors preceding it, and set the products below the 7; so shall we have all the factors or divisors of the given number 210, which are these, viz,

			210

2, 3, 5, 6, 7, 10, 14, 15, 21, 30, 35, 42, 70, 105.

A table containing every divisor of every number from 1 to 10,000, was given by Anjema, and was reprinted in London in 1747. And a much more extensive table of this kind is given in the second edition of Vega's tables, where also is a table of all prime numbers to 400,000.

PRIME *Vertical*, is that vertical circle, or azimuth, which is perpendicular to the meridian, and passes through the east and west points of the horizon.

PRIME *Verticals*, in Dialling, or PRIME-*Vertical* Dials, are those that are projected on the plane of the prime vertical circle, or on a plane parallel to it. These are otherwise called direct, erect, north, or south dials.

PRIME *of the Moon*, is the new moon at her first appearance, for about 3 days after her change. It means also the GOLDEN *Number;* which see.

PRIMUM *Mobile*, in the Ptolemaic Astronomy, is supposed to be a vast sphere, whose centre is that of the world, and in comparison of which the earth is but a point. This they describe as including all other spheres within it, and giving motion to them, turning itself and all the rest quite round in 24 hours.

PRINCIPAL, in Arithmetic, or in Commerce, is the sum lent upon interest, either simple or compound.

PRINCIPAL *Point*, in Perspective, is a point in the perspective plane, upon which falls the principal ray, or line from the eye perpendicular to the plane. This point is in the intersection of the horizontal and vertical planes; and is also called the point of sight, and point of the eye, or centre of the picture, or again the point of concurrence.

PRINCIPAL *Ray*, in Perspective, is that which passes from the spectator's eye perpendicular to the picture or perspective plane, and so meeting it in the principal point.

PRINGLE (*Sir* JOHN), Baronet, the late worthy president of the Royal Society, was born at Stichel-house, in the county of Roxburgh, North Britain, April 10, 1707. His father was Sir John Pringle, of Stichel, Bart. and his mother Magdalen Elliott, was sister to Sir Gilbert Elliot, of Stobs, Baronet. He was the youngest of several sons, three of whom, besides himself, arrived to years of maturity. After receiving his grammatical education at home, he was sent to the university of St. Andrews, where having staid some years, he removed to Edinburgh in 1727, to study physic, that being the profession which he now determined to follow. He staid however only one year at Edinburgh, being desirous of going to Leyden, which was then the most celebrated school for medicine in Europe. Dr. Boerhaave, who had brought that university into great reputation, was considerably advanced in years, and Mr. Pringle was desirous of benefiting by that great man's lectures. After having gone through his proper course of studies at Leyden, he was admitted, in 1730, to his doctor of physic's degree; upon which occasion his inaugural dissertation, De Marcore Senili, was printed. On quitting Leyden, Dr. Pringle returned and settled at Edinburgh as a physician, where, in 1734, he was appointed, by the magistrates and council of the city, to be joint professor of pneumatics and moral philosophy with Mr. Scott, during this gentleman's life, and sole professor after his decease; being also admitted at the same time a member of the university. In discharging the duties of this new employment, his text-book was Puffendorff De Officio Hominis et Civis; agreeably to the method he pursued through life, of making fact and experiment the basis of science.

Dr. Pringle continued in the practice of Physic at Edinburgh, and in duly performing the office of professor, till 1742, when he was appointed physician to the earl of Stair, who then commanded the British army. By the interest of this nobleman, Dr. Pringle was constituted, the same year, physician to the military hospital in Flanders, with a salary of 20 shillings a-day, and the right to half-pay for life. On this occasion he was permitted to retain his professorship of moral philosophy; two gentlemen, Messrs. Muirhead and Cleghorn teaching in his absence, as long as he requested it. The great attention which Dr. Pringle paid to his duty as an army physician, is evident from every page of his Treatise on the Diseases of the Army, in the execution of which office he was sometimes exposed to very imminent dangers. He soon after also met with no small affliction in the retirement of his great friend the earl of Stair, from the army. He offered to resign with his noble patron, but was not permitted: he was therefore obliged to content himself with testifying his respect and gratitude to him, by accompanying the earl 40 miles on his return to England; after which he took leave of him with the utmost regret.

But though Dr. Pringle was thus deprived of the immediate protection of a nobleman who knew and esteemed his worth, his conduct in the duties of his station procured him effectual support. He attended the army in Flanders through the campaign of 1744, and so powerfully recommended himself to the duke of Cumberland, that in the spring following he had a commission, appointing him physician-general to the king's forces in the Low-Countries, and parts beyond the seas; and on the next day he received a second commission from the duke, constituting him physician to the royal hospitals in those countries. In consequence of these promotions, he the same year resigned his professorship in the university of Edinburgh.

In 1745 he was also with the army in Flanders; but was recalled from that country in the latter end of the year, to attend the forces which were to be sent against the rebels in Scotland. At this time he had the honour of being chosen F. R. S. and the Society had good reason to be pleased with the addition of such a member. In the beginning of 1746, Dr. Pringle accompanied, in his official capacity, the duke of Cumberland in his expedition against the rebels; and remained with the forces, after the battle of Culloden, till their return to England the following summer. In 1747 and 1748, he again attended the army abroad; but in the autumn of 1748, he embarked with the forces for England, on the signing of the treaty of Aix-la-Chapelle.

From that time he mostly resided in London, where, from his known skill and experience, and the reputation he had acquired, he might reasonably expect to succeed as a physician. In 1749 he was appointed physician in ordinary to the duke of Cumberland. And in 1750 he published, in a letter to Dr. Mead, Observations on the Gaol or Hospital Fever: this piece, with some alterations, was afterwards included in his grand work on the Diseases of the Army.

In this and the two following years Dr. Pringle communicated to the Royal Society his celebrated Experiments upon Septic and Antiseptic Substances, with Remarks relating to their Use in the Theory of Medicine; some of which were printed in the Philosophical Transactions, and the whole were subjoined, as an appendix, to his Observations on the Diseases of the Army. Those experiments procured for the ingenious author the honour of Sir Godfrey Copley's gold medal; besides gaining him a high and just reputation as an experimental philosopher. He gave also many other curious papers to the Royal Society: thus, in 1753, he presented, An Account of several Persons seized with the Gaol Fever by working in Newgate; and of the Manner by which the Infection was communicated to one entire Family; in the Philos. Trans. vol. 48. His next communication was, A remarkable case of Fragility, Flexibility, and Dissolution of the Bones; in the same vol.—In the 49th volume, are accounts which he gave of an Earthquake felt at Brussels; of another at Glasgow and Dunbarton; and of the Agitation of the Waters, Nov. 1, 1756, in Scotland and at Hamburgh.—The 50th volume contains his Observations on the Case of lord Walpole, of Woollerton; and a Relation of the Virtues of Soap, in Dissolving the Stone.—The next volume is enriched with two of the doctor's articles, of considerable length, as well as value. In the first, he hath collected, digested, and related, the different accounts that had been given of a very extraordinary Fiery Meteor, which appeared the 26th of November 1758; and in the second he has made a variety of remarks upon the whole, displaying a great degree of philosophical sagacity.—Besides his communications in the Philosophical Transactions, he gave, in the 5th volume of the Edinburgh Medical Essays, an account of the Success of the Vitrum ceratum Antimonii.

In 1752, Dr. Pringle married Charlotte, the second daughter of Dr. Oliver, an eminent physician at Bath: a connexion which however did not last long, the lady dying in the space of a few years. And nearly about the time of his marriage, he gave to the public the first edition of his Observations on the Diseases of the Army; which afterwards went through many editions with improvements, was translated into the French, the German, and the Italian languages, and deservedly gained the author the highest credit and encomiums. The utility of this work however was of still greater importance than its reputation. From the time that the doctor was appointed a physician to the army, it seems to have been his grand object to lessen, as far as lay in his power, the calamities of war; nor was he without considerable success in his noble and benevolent design. The benefits which may be derived from our author's great work, are not solely confined to gentlemen of the medical profession. General Melville, a gentleman who united with his military abilities the spirit of philosophy, and the feelings of humanity, was enabled, when governor of the Neutral Islands, to be singularly useful, in consequence of the instructions he had received from Dr. Pringle's book, and from personal conversation with him. By taking care to have his men always lodged in large, open, and airy apartments, and by never letting his forces remain long enough in swampy places to be injured by the noxious air which they are subject to, the general was the happy instrument of saving the lives of 700 soldiers.

Though Dr. Pringle had not for some years been called abroad, he still held his place of physician to the army; and in the war that began in 1755, he attended the camps in England during three seasons. In 1758, however, he entirely quitted the service of the army; and being now determined to fix wholly in London, he was the same year admitted a licenciate of the college of physicians.—After the accession of king George the 3d to the throne of Great Britain, Dr. Pringle was appointed, in 1761, physician to the queen's household; and this honour was succeeded, by his being constituted, in 1763, physician extraordinary to the queen. The same year he was chosen a member of the Academy of Sciences at Haarlem, and elected a fellow of the Royal College of Physicians in London.—In 1764, on the decease of Dr. Wollaston, he was made physician-in-ordinary to the queen. In 1766 he was elected a foreign member, in the physical line, of the Royal Society of Sciences at Gottingen, and the same year he was raised to the dignity of a baronet of Great-Britain. In 1768 he was appointed physician in ordinary to the late princess-dowager of Wales.

After having had the honour to be several times elected into the council of the Royal Society, sir John Pringle was at length, viz, Nov. 30, 1772, in consequence of the death of James West, esq. elected president of that learned body. His election to this high station, though he had so respectable a character as the late sir James Porter for his opponent, was carried by a very considerable majority. Sir John Pringle's conduct in this honourable station fully justified the choice the Society made of him as their president. By his equal, impartial, and encouraging behaviour, he secured the good will and best exertions of all for the general benefit of science, and true interests of the Society, which in his time was raised to the pinnacle of honour and credit. Instead of splitting the members into opposite parties, by cruel, unjust, and tyrannical conduct, as has sometimes been the case, to the ruin of the best interests of the Society, sir John Pringle cherished and happily united the endeavours of all, collecting and directing the energy of every one to the common good of the whole. He happily also struck out a new way to distinction and usefulness, by the discourses which were delivered by him, on the annual assignment of sir Godfrey Copley's medal. This gentleman had originally bequeathed five guineas, to be given at each anniversary meeting of the Royal Society, by the determination of the president and council, to the person who should be the author of the best paper of experimental observations for the year. In process of time, this pecuniary reward, which could never be an important consideration to a man of an enlarged and philosophical mind, however narrow his circumstances might be, was changed into the more liberal form of a gold medal; in which form it is become a truly honourable mark of distinction, and a just and laudable object of ambition. No doubt it was always usual for the president, on the delivery of the medal, to pay some compliment to the gentleman on whom it was bestowed; but the custom of making a set speech on the occasion, and of entering into the history of that part of philosophy to which the experiments, or the subject of the paper related, was first introduced by Martin Folkes, esq. The discourses however which he and his successors delivered, were very short, and were only inserted in the minute-books of the Society. None of them had ever been printed before sir John Pringle was raised to the chair. The first speech that was made by him being much more elaborate and extended than usual, the publication of it was desired; and with this request, it is said, he was the more ready to comply, as an absurd account of what he had delivered had appeared in a newspaper. Sir John was very happy in the subject of his first discourse. The discoveries in magnetism and electricity had been succeeded by the inquiries into the various species of air. In these inquiries, Dr. Priestley, who had already greatly distinguished himself by his electrical experiments, and his other philosophical pursuits and labours, took the principal lead. A paper of his, entitled, Observations on different Kinds of Air, having been read before the Society in March 1772, was adjudged to be deserving of the gold medal; and sir John Pringle embraced with pleasure the occasion of celebrating the important communications of his friend, and of relating with accuracy and fidelity what had previously been discovered upon the subject.

It was not intended, we believe, when sir John's first speech was printed, that the example should be followed: but the second discourse was so well received by the Society, that the publication of it was unanimously requested. Both the discourse itself, and the subject on which it was delivered, merited such a distinction. The composition of the second speech is evidently superior to that of the former one; sir John having probably been animated by the favourable reception of his first effort. His account of the Torpedo, and of Mr. Walsh's ingenious and admirable experiments relative to the electrical properties of that extraordinary fish, is singularly curious. The whole discourse abounds with ancient and modern learniug, and exhibits the worthy president's knowledge in natural history, as well as in medicine, to great advantage.

The third time that he was called upon to display his abilities at the delivery of the annual medal, was on a very beautiful and important occasion. This was no less than Mr. Maskelyne's successful attempt completely to establish Newton's system of the universe, by his observations made on the Mountain Schihallien, for finding its attraction. Sir John laid hold of this opportunity to give a perspicuous and accurate relation of the several hypotheses of the ancients, with regard to the revolutions of the heavenly bodies, and of the noble discoveries with which Copernicus enriched the astronomical world. He then traces the progress of the grand principle of gravitation down to sir Isaac's illustrious confirmation of it; to which he adds a concise account of Messrs. Bouguer's and Condamine's experiment at Chimboraço, and of Mr. Maskelyne's at Schihallien. If any doubts still remained with respect to the truth of the Newtonian system, they were now completely removed.

Sir John Pringle had reason to be peculiarly satisfied with the subject of his fourth discourse; that subject being perfectly congenial to his disposition and studies. His own life had been much employed in pointing out the means which tended not only to cure, but to prevent the diseases of mankind; and it is probable, from his intimate friendship with captain Cook, that he might suggest to that sagacious commander some of the rules which he followed, in order to preserve the health of the crew of his ship, during his voyage round the world. Whether this was the case, or whether the method pursued by the captain to attain so salutary an end, was the result alone of his own reflections, the success of it was astonishing; and this celebrated voyager seemed well entitled to every honour which could be bestowed. To him the Society assigned their gold medal, but he was not present to receive the honour. He was gone out upon the voyage, from which he never returned: but in this last voyage he continued equally successful in maintaining the health of his men.

The learned president, in his fifth annual dissertation, had an opportunity of displaying his knowledge in a way in which it had not hitherto appeared. The discourse took its rise from the adjudication of the prize medal to Mr. Mudge, then an eminent surgeon at Plymouth, on account of his valuable paper, containing Directions for making the best Composition for the Metals of Reflecting Telescopes, together with a Description of the Process for Grinding, Polishing, and giving the Great Speculum the true Parabolic Form. Sir John has accurately related a variety of particulars, concerning the invention of reflecting telescopes, the subsequent improvements of these instruments, and the state in which Mr. Mudge found them, when he first set about working them to a greater perfection, till he had truly realized the expectation of Newton, who, above an hundred years ago, presaged that the public would one day possess a parabolic speculum, not accomplished by mathematical rules, but by mechanical devices.

Sir John Pringle's sixth and last discourse, to which he was led by the assignment of the gold medal to myself, on account of my paper entitled, The Force of fired Gunpowder, and the Initial Velocity of Cannon Balls, determined by Experiments, was on the theory of gunnery. Though sir John had so long attended the army, this was probably a subject to which he had heretofore paid very little attention. We cannot however help admiring with what perspicuity and judgment he stated the progress that was made, from time to time, in the knowledge of projectiles, and the scientific perfection to which it has been said to be carried in my paper. As sir John Pringle was not one of those who delighted in war, and in the shedding of human blood, he was happy in being able to show that even the study of artillery might be useful to mankind; and therefore this is a topic which he has not forgotten to mention. Here ended our author's discourses on the delivery of sir Godfrey Copley's medal, and his presidency over the Royal Society at the same time, the delivering that medal into my hand being the last office he ever performed in that capacity; a ceremony which was attended by a greater number of the members, than had ever met together before upon any other occasion. Had he been permitted to preside longer in that chair, he would doubtless have found other occasions of displaying his acquaintance with the history of philosophy. But the opportunities which he had of signalizing himself in this respect were important in themselves, happily varied, and sufficient to gain him a solid and lasting reputation.

Several marks of literary distinction, as we have already seen, had been conferred on sir John Pringle, before he was raised to the president's chair. But after that event they were bestowed upon him in great abundance, having been elected a member of almost all the literary societies and institutions in Europe. He was also, in 1774, appointed physician-extraordinary to the king.

It was at rather a late period of life when sir John Pringle was chosen to be president of the Royal Society, being then 65 years of age. Considering therefore the great attention that was paid by him to the various and important duties of his office, and the great pains he took in the preparation of his discourses, it was natural to expect that the burthen of his honourable station should grow heavy upon him in a course of time. This burthen, though not increased by any great addition to his life, for he was only 6 years president, was somewhat augmented by the accident of a fall in the area in the back part of his house, from which he received some hurt. From these circumstances some persons have affected to account for his resigning the chair at the time when he did. But sir John Pringle was naturally of a strong and robust frame and constitution, and had a fair prospect of being well able to discharge the duties of his situation for many years to come, had his spirits not been broken by the most cruel harassings and baitings in his office. His resolution to quit the chair originated from the disputes introduced into the Society, concerning the question, whether pointed or blunt electrical conductors are the most efficacious in preserving buildings from the pernicious effects of lightning, and from the cruel circumstances attending those disputes. These drove him from the chair. Such of those circumstances as were open and manifest to every one, were even of themselves perhaps quite sufficient to drive him to that resolution. But there were yet others of a more private nature, which operated still more powerfully and directly to produce that event; which may probably hereafter be laid before the public.

His intention of resigning however, was disagreeable to his friends, and the most distinguished members of the Society, who were many of them perhaps ignorant of the true motive for it. Accordingly, they earnestly solicited him to continue in the chair; but, his resolution being fixed, he resigned it at the anniversary meeting in 1778, immediately on delivering the medal, at the conclusion of his speech, as mentioned above.

Though sir John Pringle thus quitted his particular relation to the Royal Society, and did not attend its meetings so constantly as he had formerly done, he still retained his literary connexions in general. His house continued to be the resort of ingenious and philosophical men, whether of his own country, or from abroad; and he was frequent in his visits to his friends. He was held in particular esteem by eminent and learned foreigners, none of whom came to England without waiting upon him, and paying him the greatest respect. He treated them, in return, with distinguished civility and regard. When a number of gentlemen met at his table, foreigners were usually a part of the company.

In 1780 sir John spent the summer on a visit to Edinburgh; as he did also that of 1781; where he was treated with the greatest respect. In this last visit he presented to the Royal College of Physicians in that city, the result of many years labour, being ten folio volumes of Medical and Physical Observations, in manuscript, on condition that they should neither be published, nor lent out of the library of the college on any account whatever. He was at the same time preparing two other volumes, to be given to the university, containing the formulas referred to in his annotations. He returned again to London, and continued for some time his usual course of life, receiving and paying visits to the most eminent literary men, but languishing and declining in his health and spirits, till the 18th of January 1782, when he died, in the 75th year of his age; the account of his death being every where received in a manner which showed the high sense that was entertained of his merit.

Sir John Pringle's eminent character as a practical physician, as well as a medical author, is so well known, and so universally acknowledged, that an enlargement upon it cannot be necessary. In the exercise of his profession he was not rapacious; being ready, on various occasions, to give his advice without pecuniary views. The turn of his mind led him chiefly to the love of science, which he built on the firm basis of fact. With regard to philosophy in general, he was as averse to theory, unsupported by experiments, as he was with respect to medicine in particular. Lord Bacon was his favourite author; and to the method of investigation recommended by that great man, he steadily adhered. Such being his intellectual character, it will not be thought surprising that he had a dislike to Plato; and that to metaphysical disquisitions he lost all regard in the latter part of his life.

Sir John had no great fondness for poetry: he had not even any distinguished relish for the immortal Shakespear: at least he seemed too highly sensible of the defects of that illustrious bard, to give him the proper degree of estimation. Sir John had not in his youth been neglectful of philological inquiries, nor did he desert them in the last stages of his life, but cultivated even to the last a knowledge of the Greek language. He paid a great attention to the French language; and it is said that he was fond of Voltaire's critical writings. Among all his other pursuits, he never forgot the study of the English language. This he regarded as a matter of so much consequence, that he took uncommon pains with regard to the style of his compositions; and it cannot be denied, that he excelled in perspicuity, correctness, and propriety of expression. His six discourses in particular, delivered at the annual meetings of the Royal Society, on occasion of the prize medals, have been universally admired as elegant compositions, as well as critical and learned dissertations. And this characteristic of them, seemed to increase and heighten, from year to year: a circumstance which argues rather an improvement of his faculties, than any decline of them, and that even after the accident which it was pretended occasioned his descent from the president's chair. So excellent indeed were these compositions esteemed, that envy used to asperse his character with the imputation of borrowing the hand of another in those learned discourses. But how false such aspersion was, I, and I believe most of the other gentlemen who had the honour of receiving the annual medal from his hands, can fully testify. For myself in particular, I can witness for the last, and perhaps the best, that on the theory and improvements in gunnery, having been present or privy to his composition of every part of it.—Though our author was not fond of poetry, he had a great affection for the sister art music: of this he was not merely an admirer, but became so far a practitioner in it, as to be a performer on the violoncello, at a weekly concert given by a society of gentlemen at Edinburgh. Besides a close application to medical and philosophical science, during the latter part of his life, he devoted much time to the study of divinity: this being with him a very favourite and interesting object.

If, from the intellectual, we pass on to the moral character of sir John Pringle, we shall find that the ruling feature of it was integrity: and by this principle he was uniformly actuated in the whole of his conduct and behaviour. He was equally distinguished for his sobriety, having been heard to declare, that he had never once in his life been intoxicated with liquor. In his friendships, he was ardent and steady. The intimacies which were formed by him, in the early part of his life, continued unbroken to the decease of the gentlemen with whom they were made; and were kept up by a regular correspondence, and by all the good offices that lay in his power.

With regard to sir John's external manner of deportment, he paid a very respectful attention to those who were honoured with his friendship and esteem, and to such strangers as came to him well recommended. Foreigners in particular had good reason to be satisfied with the uncommon pains which he took to show them every mark of civility and regard. He had however at times somewhat of a dryness and reserve in his behaviour, which had the appearance of coldness; and this was the case when he was not perfectly pleased with the persons who were introduced to him, or who happened to be in his company. His sense of integrity and dignity would not permit him to adopt that false and superficial politeness, which treats all men alike, though ever so different in point of real estimation and merit, with the same show of cordiality and kindness. He was above assuming the profession, without the reality of respect.

PRISM, in Geometry, is a body, or solid, whose two ends are any plane figures which are parallel, equal, and similar; and its sides, connecting those ends, are parallelograms.—Hence, every section parallel to the ends, is the same kind of equal and similar figure as the ends themselves are; and the prism may be considered as generated by the parallel motion of this plane figure.

Prisms take their several particular names from the figure of their ends. Thus, when the end is a triangle, it is a triangular prism; when a square, a square prism; when a pentagon, a pentagonal prism; when a hexagon, a hexagonal prism; and so on. And hence the denomination prism comprises also the cube and parallelopipedon, the former being a square prism, and the latter a rectangular one. And even a cylinder may be considered as a round prism, or one that has an infinite number of sides. Also a prism is said to be regular or irregular, according as the figure of its end is a regular or an irregular polygon.

The axis of a prism, is the line conceived to be drawn lengthways through the middle of it, connecting the centre of one end with that of the other end.

Prisms, again, are either right or oblique.

A *Right* Prism is that whose sides, and its axis, are perpendicular to its ends; like an upright tower.

An *Oblique* Prism, is when the axis and sides are oblique to the ends; so that, when set upon one end, it inclines on one side, like an inclined tower.

The principal properties of prisms, are,

1. That all prisms are to one another in the ratio compounded of their bases and heights.

2. Similar prisms are to one another in the triplicate ratio of their like sides.

3. A prism is triple of a pyramid of equal base and height; and the solid content of a prism is found by multiplying the base by the perpendicular height.

4. The upright surface of a right prism, is equal to a rectangle of the same height, and its breadth equal to the perimeter of the base or end. And therefore such upright surface of a right prism, is found by multiplying the perimeter of the base by the perpendicular height. Also the upright surface of an oblique prism is found by multiplying the perimeter of the base by the slant height. And if to the upright surface be added the areas of the two ends, the sum will be the whole surface of the prism.

Prism, in Dioptrics, is a piece of glass in form of a triangular prism: which is much used in experiments concerning the nature of light and colours.—The use and phenomena of the prism arise from its sides not being parallel to each other; whence it separates the rays of light in their passage through it, by coming through two sides of one and the same angle.

The more general of these phenomena are enumerated and illustrated under the article Colour; which are sufficient to prove, that colours do not either consist in the contorsion of the globules of light, as Descartes imagined; nor in the obliquity of the pulses of the ethereal matter, as Hooke fancied; nor in the constipation of light, and its greater or less concitation, as Dr. Barrow conjectured; but that they are original and unchangeable properties of light itself.

PRISMOID, is a solid, or body, somewhat resembling a prism, but that its ends are any dissimilar parallel plane figures of the same number of sides; the upright sides being trapezoids.—If the ends of the prismoid be bounded by dissimilar curves, it is sometimes called a cylindroid.

PROBABILITY *of an Event*, in the Doctrine of Chances, is the ratio of the number of chances by which the event may happen, to the number by which it may both happen and fail. So that, if there be constituted a fraction, of which the numerator is the number of chances for the event's happening, and the denominator the number for both happening and failing, that fraction will properly express the value of the probability of the event's happening. Thus, if an event have 3 chances for happening, and 2 for failing, the sum of which being 5, the fraction $\frac{3}{5}$ will properly represent the probability of its happening, and may be taken to be the measure of it. The same thing may be said of the probability of failing, which will likewise be measured by a fraction, whose numerator is the number of chances by which it may fail, and its denominator the whole number of chances both for its happening and failing: so the probability of the failing of the above event, which has 2 chances to fail, and 3 to happen, will be expressed or measured by the fraction $\frac{2}{5}$.

Hence, if there be added together the fractions which express the probability for both happening and failing, their sum will always be equal to unity or 1; since the sum of their numerators will be equal to their common denominator. And since it is a certainty that an event will either happen or fail, it follows that a certainty, which may be considered as an infinitely great degree of probability, is fitly represented by unity. If it be required, what the probability is of an event happening in two trials, then we must estimate the probability of its failing twice, which taken from unity will be the probability of its happening. Thus if it was asked what is the probability of a person's casting an ace in two throws with a die of 6 faces. Here the probability of its failing the first time is $\frac{5}{6}$, there being 5 sides that may come up without the ace; also the probability of its failing the second throw is the same, therefore $\frac{5}{6} \times \frac{5}{6} = \frac{25}{36}$ the probability of its failing both times, and consequently $\frac{36}{36} - \frac{25}{36} = \frac{11}{36}$ is the probability of its coming up one time at least in two throws. This circumstance is not readily comprehended by persons unskilled in the doctrine of chances; for, say they, the probability of its coming up the first time being $\frac{1}{6}$, and the probability of its coming up the second time being also $\frac{1}{6}$, therefore the two chances together must be $\frac{1}{6} + \frac{1}{6} = \frac{1}{3}$. But in this they deceive themselves, since it is not certain that they will have to throw a second time. See Simpson's or Demoivre's Doctrine of Chances; also Bernoulli's Ars Conjectandi; Monmort's Analyse des Jeux de Hasard; or M. De Parcieu's Essais sur les Probabilites de la Vie humaine. See also CHANCES, EXPECTATION, and GAMING.

PROBABILITY *of Life*. See EXPECTATION *of Life*, and LIFE-*Annuities*.

PROBLEM, in Geometry, is a proposition in which some operation or construction is required. As, to bisect a line, to make a triangle, to raise a perpendicular, to draw a circle through three points, &c. A problem, according to Wolfius, consists of three parts: The proposition, which expresses what is to be done; the resolution or solution, in which are orderly rehearsed the several steps of the process or operation; and the demonstration, in which it is shown, that by doing the several things prescribed in the resolution, the thing required is obtained.

PROBLEM, in Algebra, is a proposition which requires some unknown truth to be investigated or discovered; and the truth of the discovery demonstrated.

PROBLEM, *Kepler's*. See KEPLER'S *Problem*.

PROBLEM, *Determinate, Diophantine, Indeterminate, Limited, Linear, Local, Plane, Solid, Sursolid*, and *Unlimited*. See the adjectives.

Deliacal PROBLEM, in Geometry, is the doubling of a cube. This amounts to the same thing as the finding of two mean proportionals between two given lines: whence this also is called the Deliacal Problem. See DUPLICATION.

PROCLUS, an eminent philosopher and mathematician among the later Platonists, was born at Constantinople in the year 410, of parents who were both able and willing to provide for his instruction in all the various branches of learning and knowledge. He was first sent to Xanthus, a city of Lycia, to learn grammar: from thence to Alexandria, where he was under the best masters in rhetoric, philosophy, and mathematics: and from Alexandria he removed to Athens, where he attended the younger Plutarch, and Syrian, both of them celebrated philosophers. He succeeded the latter in the government of the Platonic school at Athens; where he died in 485, at 75 years of age.

Marinus of Naples, who was his successor in the school, wrote his life; the first perfect copy of which was published, with a Latin version and notes, by Fabricius at Hamburgh, 1700, in 4to; and afterwards subjoined to his Bibliotheca Latina, 1703, in 8vo. Marinus was also author of a learned commentary on Euclid's Data.

Proclus wrote a great number of pieces, and on many different subjects; as, commentaries on philosophy, mathematics, and grammar; on the whole works of Homer, Hesiod, and Plato's books of the republic: he wrote also on the construction of the Astrolabe: but many of his pieces are lost; some have been published; and a few remain still in manuscript only. Of the published, there are four very elegant hymns; one to the Sun, two to Venus, and one to the Muses. There are commentaries on several pieces of Plato; on the four books of Ptolemy's work De Judiciis Astrorum; on the first book of Euclid's Elements; and on Hesiod's Opera et Dies. There are also works of Proclus on philosophical and astronomical subjects; particularly the piece De Sphera, which was published, 1620, in 4to, by Bainbridge, the Savilian professor of astronomy at Oxford. He wrote also 18 arguments against the Christians, which are still extant, and in which he attacks them on the question, whether the world be eternal? the affirmative of which he maintains.

The character of Proclus is the same as that of all the later Platonists, who it seems were not less enthusiasts and madmen, than the Christians their contemporaries, whom they resembled in this respect. Proclus was not reckoned quite orthodox by his own order: he did not adhere so rigorously, as Julian and Porphyry, to the doctrines and principles of his master; "He had," says Cudworth, "some peculiar fancies and whimsies of his own, and was indeed a confounder of the Platonic theology, and a mingler of much unintelligible stuff with it."

PROCYON, in Astronomy, a fixed star, of the second magnitude, in Canis Minor, or the Little Dog.

PRODUCING, in Geometry, denotes the continuing a line, or drawing it farther out, till it have an assigned length.

PRODUCT, in Arithmetic, or Algebra, is the quantity arising from, or produced by, the multiplication of, two or more numbers &c together. Thus, 48 is the product of 6 multiplied by 8.—In multiplication, unity is in proportion to one factor, as the other factor is to the product. So 1 : 6 : : 8 : 48.

In algebra, the product of simple quantities is expressed by joining the letters together like a word, and prefixing the product of the numeral coefficients: So the product of a and b is ab, of $3a$ and $4bc$ is $12abc$. But the product of compound factors or quantities is expressed by setting the sign of multiplication between them, and binding each compound factor in a vinculum: so the product of $2a + 3b$ and $a - 4c$ is $(2a + 3b) \times (a - 4c)$.

In geometry, a rectangle answers to a product, its length and breadth being the two factors; because the numbers expressing the length and breadth being multiplied together, produce the content or area of the rectangle.

The term product, or continual product, is also sometimes used when the factors are more than two.

In algebra there are several curious properties relating to the particular forms of the product of certain formulæ, which are of great importance in the theory of numbers, and the indeterminate analysis; the most remarkable of which are as follows:

1. The product of a sum of two squares by double a square, is also the sum of two squares.

For $(x^2 + y^2) . 2z^2 = (x + y)^2 . z^2 + (x - y)^2 . z^2$.

2. The product of the sum of two squares, by the sum of two squares, is itself the sum of two squares.

For $(x^2 + y^2) . (x'^2 + y'^2) = \begin{cases} (xx' + yy')^2 + (xy' - x'y)^2 \\ \text{or } (xx' - yy')^2 + (xy' + x'y)^2 \end{cases}$

The product may therefore be divided into two squares two different ways. And if this product be again multiplied by the sum of two squares, the product may be divided into two squares four different ways; and so on.

3. The product of the sum of three squares by the sum of two squares, is the sum of four squares.

For $(x^2 + y^2 + z^2) \times (x'^2 + y'^2) =$
$(xx' + yy')^2 + (xy' - x'y)^2 + z^2x'^2 + z^2y'^2$.

4. The product of the sum of four squares by double a square, is also the sum of four squares.

For $(x^2 + y^2 + z^2 + w^2) . 2z^2 =$
$z^2((x + y)^2 + (x - y)^2 + (z + w)^2 + (z - w)^2) =$
$z^2(x + y)^2 + z^2 (x - y)^2 + z^2 (z + w)^2 + z^2 (z - w)^2$.

5. The product of the sum of four squares, by the sum of four squares, is itself the sum of four squares.

For $(w^2 + x^2 + y^2 + z^2) . (w'^2 + x'^2 + y'^2 + z'^2)$
$= (ww' + xx' + yy' + zz')^2 + (wx' - xw' + yz' - zy')^2$
$+ (wy' - xz' - yw' + zx')^2 + (wz' + xy' - yx' - zw')^2$.

6. The two formulæ $x^2 + y^2 + z^2$ and $x'^2 + y'^2 + 2z'^2$ are so related to each other, that double the one produces the other.

For $2 . (x^2 + y^2 + z^2) = 2x^2 + 2y^2 + 2z^2 =$
$(x + y)^2 + (x - y)^2 + 2z^2$; and $2 (x'^2 + y'^2 + 2z^2) =$
$2x'^2 + 2y'^2 + 4z'^2 = (x' + y')^2 + (x' - y')^2 + 4z'^2$.

The truth of the above theorems will be seen immediately by the developement of each respective formula.

PROFILE, in Architecture, the figure or draught of a building, fortification, or the like; in which are expressed the several heights, widths, and thicknesses, such as they would appear, were the building cut down perpendicularly from the roof to the foundation. Whence the profile is also called the section, and sometimes the orthographical section; and by Vitruvius the sciography. In this sense, profile amounts to the same thing with elevation; and so stands opposed to a plan or ichnography.

PROFILE is also used for the contour, or outline of a figure, building, member of architecture, or the like; as a base, a cornice, &c.

PROGRESSION, an orderly advancing or proceeding in the same manner, course, tenor, proportion, &c.

Progression is either arithmetical, geometrical, or harmonical.

Arithmetical PROGRESSION, is a series of quantities proceeding by continued equal differences, either increasing or decreasing. Thus,

increasing 1, 3, 5, 7, 9, &c, or
decreasing 21, 18, 15, 12, 9, &c;

where the former progression increases continually by the common difference 2, and the latter decreases continually by the common difference 3.

1. And hence, to construct an arithmetical progression, from any given first term, with a given common difference; add the common difference to the first term, to give the 2d; to the 2d, to give the 3d; to the 3d, to give the 4th; and so on; when the series is ascending or increasing: but subtract the common difference continually, when the series is a descending one.

2. The chief property of an arithmetical progression, and which arises immediately from the nature of its construction, is this; that the sum of its extremes, or first and last terms, is equal to the sum of every pair of intermediate terms that are equidistant from the extremes, or to the double of the middle term when there is an uneven number of the terms.

Thus,	1,	3,	5,	7,	9,	11,	13,
	13,	11,	9,	7.	5,	3,	1,
Sums	14	14	14	14	14	14	14,

where the sum of every pair of terms is 14.

Also,	a,	$a + d$,	$a + 2d$,	$a + 3d$,	$a + 4d$,
	$a + 4d$,	$a + 3d$,	$a + 2d$,	$a + d$,	a
sums	$2a + 4d$,	$2a + 4d$,	$2a + 4d$,	$2a + 4d$,	$2a + 4d$.

3. And hence it follows, that double the sum of all the terms in the series, is equal to the sum of the two extremes multiplied by the number of the terms; and consequently, that the single sum of all the terms of the series, is equal to half the said product. So the sum of the 7 terms, 1, 3, 5, 7, 9, 11, 13, is $(1 + 13) \times \frac{7}{2} = \frac{14}{2} \times 7 = 49$. And the sum of the five terms
$a, a + d, a + 2d, a + 3d, a + 4d$, is $(2a + 4d) \times \frac{5}{2}$.

4. Hence also, if the first term of the progression be 0, the sum of the series will be equal to half the product of the last term multiplied by the number of terms: i. e. the sum of
$0 + d + 2d + 3d + 4d \cdots\cdots (n - 1)d = \frac{1}{2}n . (n - 1)d$,
where n is the number of terms, supposing 0 to be one of them. That is, in other words, the sum of an arithmetical progression, whether finite or infinite, whose first term is 0, is to the sum of as many times the greatest term, in the ratio of 1 to 2.

5. In like manner, the sum of the squares of the terms of such a series, beginning at 0, is to the sum of as many terms each equal to the greatest, in the ratio of 1 to 3. And

6. The sum of the cubes of the terms of such a series, is to the sum of as many times the greatest term, in the ratio of 1 to 4.

7. And universally, if every term of such a progression be raised to the m power, then the sum of all those powers will be to the sum of as many terms equal to the greatest, in the ratio of 1 to $m + 1$. That is,

the sum $0 + d + 2d + 3d \text{-------} l$,
is to $l^m + l^m + l^m + l^m \text{-------} l^m$,

in the ratio of 1 to $m + 1$.

8. A synopsis of all the theorems, or relations, in an arithmetical progression, between the extremes or first and last term, the sum of the series, the number of terms, and the common difference, is as follows:

viz, if a denote the least term,
z the greatest term,
d the common difference,
n the number of terms,
s the sum of the series;

then will each of these five quantities be expressed in terms of the others, as below:

$$a = z - (n-1)\,d = \frac{2s}{n} - z = \frac{s}{n} - \frac{n-1}{2}d = \sqrt{((\tfrac{1}{2}d + z)^2 - 2ds)} + \tfrac{1}{2}d.$$

$$z = a + (n-1)\,d = \frac{2s}{n} - a = \frac{s}{n} + \frac{n-1}{2}d = \sqrt{((\tfrac{1}{2}d - a)^2 + 2ds)} - \tfrac{1}{2}d.$$

$$d = \frac{z-a}{n-1} = \frac{s-na}{n-1}\cdot\frac{2}{n} = \frac{nz-s}{n-1}\cdot\frac{2}{n} = \frac{z+a\,.\,z-a}{2s-a-z}.$$

$$n = \frac{z-a}{d} + 1 = \frac{2s}{a+z} = \frac{\tfrac{1}{2}d - a + \sqrt{((\tfrac{1}{2}d - a)^2 + 2ds)}}{d} = \frac{\tfrac{1}{2}d + z - \sqrt{((\tfrac{1}{2}d + z)^2 - 2ds)}}{d}.$$

$$s = \frac{a+z}{2}n = \frac{a+z}{2}\cdot\frac{z-a+d}{d} = \frac{2a+(n-1)d}{2}n = \frac{2z-(n-1)d}{2}n.$$

And most of these expressions will become much simpler if the first term be 0 instead of a.

Geometrical PROGRESSION, is a series of quantities proceeding in the same continual ratio or proportion, either increasing or decreasing; or it is a series of quantities that are continually proportional; or which increase by one common multiplier, or decrease by one common divisor; which common multiplier or divisor is called the common ratio. As,

increasing, 1, 2, 4, 8, 16, &c,
decreasing, 81, 27, 9, 3, 1, &c;

where the former progression increases continually by the common multiplier 2, and the latter decreases by the common divisor 3.

Or ascending, $a,\ ra,\ r^2a,\ r^3a$, &c,
or descending, $a,\ \frac{a}{r},\ \frac{a}{r^2},\ \frac{a}{r^3}$, &c;

where the first term is a, and common ratio r.

1. Hence, the same principal properties obtain in a geometrical progression, as have been remarked of the arithmetical one, using only multiplication in the geometricals, for addition in the arithmeticals, and division in the former for subtraction in the latter. So that, to construct a geometrical progression, from any given first term, with a given common ratio; multiply the 1st term continually by the common ratio, for the rest of the terms when the series is an ascending one; or divide continually by the common ratio, when it is a descending progression.

2. In every geometrical progression, the product of the extreme terms, is equal to the product of every pair of the intermediate terms that are equidistant from the extremes, and also equal to the square of the middle term when there is a middle one, or an uneven number of the terms.

$$\begin{array}{llllll} \text{Thus,} & 1, & 2, & 4, & 8, & 16, \\ & \underline{16} & \underline{8} & \underline{4} & \underline{2} & \underline{1} \\ \text{prod.} & 16 & 16 & 16 & 16 & 16 \\ \text{Also} & a, & ra, & r^2a, & r^3a, & r^4a, \\ & \underline{r^4a} & \underline{r^3a} & \underline{r^2a} & \underline{ra} & \underline{a} \\ \text{prod.} & r^4a^2 & r^4a^2 & r^4a^2 & r^4a^2 & r^4a^2 \end{array}$$

3. The last term of a geometrical progression, is equal to the first term multiplied, or divided, by the ratio raised to the power whose exponent is less by 1 than the number of terms in the series; so $z = ar^{n-1}$ when the series is an ascending one, or $z = \frac{a}{r^{n-1}}$, when it is a descending progression.

4. As the sum of all the antecedents, or all the terms except the least, is to the sum of all the consequents, or all the terms except the greatest, so is 1 to r the ratio. For,

if $a + ra + r^2a + r^3a$ be all except the last,
then $ra + r^2a + r^3a + r^4a$ are all except the first;

where it is evident that the former is to the latter as 1 to r, or the former multiplied by r gives the latter. So that, z denoting the last term, a the first term, and r the ratio, also s the sum of all the terms; then $s - z : s - a :: 1 : r$, or $s - a = (s - z)r$. And from this equation all the relations among the four quantities a, z, r, s, are easily derived; such as $s = \frac{rz - a}{r - 1}$; viz, multiply the greatest term by the ratio, subtract the least term from the product, then the remainder divided by 1 less than the ratio, will give the sum of the series. And if the least term a be 0, which happens when the descending progression is infinitely continued, then the sum is barely $\frac{rz}{r-1}$. As in the infinite progression $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8}$ &c, where $z = 1$, and $r = 2$, it is s or $\frac{rz}{r-1} = \frac{2}{2-1} = \frac{2}{1} = 2$.

5. The first or least term of a geometrical progression, is to the sum of all the terms, as the ratio minus 1, to the n power of the ratio minus 1; that is $a : s :: r - 1 : r^n - 1$.

Other relations among the five quantities a, z, r, n, s, where

a denotes the least term,
z the greatest term,
r the common ratio,
n the number of terms,
s the sum of the progression,

are as below; viz,

$$a = \frac{z}{r^{n-1}} = sr - (r-1)s = \frac{r-1}{r^n - 1}s.$$

$$z = ar^{n-1} = \frac{a + (r-1)s}{r} = \frac{r-1}{r^n - 1}sr^{n-1}.$$

$$r = \frac{s-a}{s-z} = \sqrt[n-1]{\frac{z}{a}}.$$

$$n = \frac{\log.\frac{rz}{a}}{\log. r} = \frac{\log.\frac{a+(r-1)s}{a}}{\log. r} = \frac{\log.\frac{rz}{rz-(r-1)s}}{\log. r} = \frac{\log.\frac{s-a}{s-z}.\frac{z}{a}}{\log.\frac{s-a}{s-z}}.$$

$$s = \frac{rz-a}{r-1} = \frac{r^n-1}{r-1}a = \frac{r^n-1}{r-1}.\frac{z}{r^{n-1}} = \frac{\sqrt[n-1]{z^n} - \sqrt[n-1]{a^n}}{\sqrt[n-1]{z} - \sqrt[n-1]{a}}.$$

And the other values of a, z, and r are to be found from these equations, viz,

$$(s-z)^{n-1}z = (s-a)^{n-1}a,$$

$$r^n - \frac{s}{a}r = 1 - \frac{s}{a},$$

$$r^n - \frac{s}{s-z}r^{n-1} = \frac{z}{s-z}.$$

Harmonical Progression, is a continued series of terms in harmonical proportion. The reciprocals of an arithmetical progression form an harmonical progression. Thus, the reciprocals of the arithmetical series 1, 2, 3, 4, 5, 6, &c give $\frac{1}{1}$, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$, $\frac{1}{6}$, &c, form an harmonical series.

For other kinds of Progression, see Proportion, and Series.

PROJECTILE, in Mechanics, is any body which, being put into a violent motion by an external force impressed upon it, is dismissed from the agent, and left to pursue its course. Such as a stone thrown out of the hand or a sling, an arrow from a bow, a ball from a gun, &c.

PROJECTILES, the science of the motion, velocity, flight, range, &c, of a projectile put into violent motion by some external cause, as the force of gunpowder, &c. This is the foundation of gunnery, under which article may be found all that relates peculiarly to that branch.

All bodies, being indifferent as to motion or rest, will necessarily continue in the state they are put into, except so far as they are retarded, and forced to change it by some new cause. Hence, a projectile, put in motion, must continue eternally to move on in the same right line, and with the same uniform or constant velocity, were it to meet with no resistance from the medium, nor had any force of gravity to encounter.

In the first case, the theory of projectiles would be very simple indeed; for there would be nothing more to do, than to compute the space passed over in a given time by a given constant velocity; or either of these, from the other two being given.

But by the constant action of gravity, the projectile is continually deflected more and more from its right-lined course, and that with an accelerated velocity; which, being combined with its projectile impulse, causes the body to move in a curvilineal path, with a variable motion, which path is the curve of a parabola, as will be proved below; and the determination of the range, time of flight, angle of projection, and variable velocity, constitutes what is usually meant by the doctrine of projectiles, in the common acceptation of the term.

What is said above however, is to be understood of projectiles moving in a non-resisting medium; for when the resistance of the air is also considered, which is enormously great, and which very much impedes the first projectile velocity, the path deviates greatly from the parabola, and the determination of the circumstances of its motion becomes one of the most complex and difficult problems in nature.

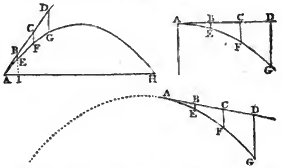
In the first place therefore it will be proper to consider the common doctrine of projectiles, or that on the parabolic theory, or as depending only on the nature of gravity and the projectile motion, as abstracted from the resistance of the medium.

About 300 years ago, philosophers took the line described by a body projected horizontally, such as a bullet out of a cannon, while the force of the powder greatly exceeded the weight of the bullet, to be a right line, after which they allowed it became a curve. Nicholas Tartaglia was the first who perceived the mistake, maintaining that the path of the bullet was a curved line through the whole of its extent. But it was Galileo who first determined what particular curve it is that a projectile describes; showing that the path of a bullet projected horizontally from an eminence, was a parabola; the vertex of which is the point where the bullet quits the cannon. And the same is proved generally, in the 2d section following, when the projection is made in any direction whatever, viz, that the curve is always a parabola, supposing the body moves in a non-resisting medium, and that gravity acts upon it in lines parallel to each other.—It is true, that this is not accurately the case, because this force always tends to the centre of gravity of the earth; but the inclination of these lines is too trifling to affect the parabolic theory of projectiles.

The Laws of the Motion of Projectiles.

I. If a heavy body be projected perpendicularly, it will continue to ascend or descend perpendicularly; because both the projecting and the gravitating force are found in the same line of direction.

II. If a body be projected in free space, either parallel to the horizon, or in any oblique direction; it will, by this motion, in conjunction with the action of gravity, describe the curve line of a parabola.



For let the body be projected from A, in the direction AD, with any uniform velocity; then in any equal portions of time it would, by that impulse alone, describe the equal spaces AB, BC, CD, &c in the line AD, if it were not drawn continually down below that line by the action of gravity. Draw BE, CF, DG, &c, in the direction of gravity, or perpendicular to the horizon; and take BE, CF, DG, &c, equal to the spaces through which the body would descend by its gravity in the same times in which it would uniformly pass over the spaces AB, AC, AD, &c, by the projectile motion. Then, since by these motions, the body is carried over the space AB in the same time as the space BE, and the space AC in the same time as the space CF, and the space AD in the same time as the space DG, &c; therefore, by the composition of motions, at the end of those times the body will be found respectively in the points E, F, G, &c, and consequently the real path of the projectile will be the curve line AEFG&c. But the spaces AB, AC, AD, &c, being described by uniform motion, are as the times of description; and the spaces BE, CF, DG, &c, described in the same times by the accelerating force of gravity, are as the squares of the times; consequently the perpendicular descents are as the squares of the spaces in AD,

that is - - - BE, CF, DG, &c,
are respectively proportional to AB^2, AC^2, AD^2, &c,

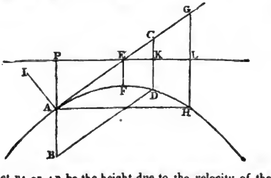
which is the same as the property of the parabola. Therefore the path of the projectile is the parabolic line AEFG &c, to which AD is a tangent at the point A.

Hence, 1. The horizontal velocity of a projectile is always the same constant quantity, in every point of the curve; because the horizontal motion is in a constant ratio to the motion in AD, which is the uniform projectile motion; viz, the constant horizontal velocity being to the projectile velocity, as radius to the cosine of the angle DAH, or angle of elevation or depression of the piece above or below the horizontal line AH.

2. The velocity of the projectile in the direction of the curve, or of its tangent, at any point A, is as the secant of its angle BAI of direction above the horizon. For the motion in the horizontal direction AI being constant, and AI being to AB as radius to the secant of the angle A; therefore the motion at A, in AB, is as the secant of the angle A.

3. The velocity in the direction DG of gravity, or perpendicular to the horizon, at any point G of the curve, is to the first uniform projectile velocity at A, as 2GD to AD. For the times of describing AD and DG being equal, and the velocity acquired by freely descending through DG being such as would carry the body uniformly over twice DG in an equal time, and the spaces described with uniform motions being as the velocities, it follows that the space AD is to the space 2DG, as the projectile velocity at A is to the perpendicular velocity at G.

III. The velocity in the direction of the curve, at any point of it, as A, is equal to that which is generated by gravity in a body freely descending through a space which is equal to one-fourth of the parameter of the diameter to the parabola at that point.



Let PA or AB be the height due to the velocity of the projectile at any point A, in the direction of the curve or tangent AC, or the velocity acquired by falling through that height; and complete the parallelogram ACDB. Then is CD = AB or AP the height due to the velocity in the curve at A; and CD is also the height due to the perpendicular velocity at D, which will therefore be equal to the former: but, by the last corollary, the velocity at A is to the perpendicular velocity at D, as AC to 2CD; and as these velocities are equal, therefore AC or BD is equal to 2CD or 2AB; and hence AB or AP is equal to $\frac{1}{4}$BD or $\frac{1}{4}$ of the parameter of the diameter AB by the nature of the parabola.

Hence, 1. If through the point P, the line PL be drawn perpendicular to AP; then the velocity in the curve at every point, will be equal to the velocity acquired by falling through the perpendicular distance of the point from the said line PL; that is, a body falling freely through

PA, acquires the velocity in the curve at A,
EF, - - - at F,
KD, - - - at D,
LH, - - - at H.

The reason of which is, that the line PL is what is called the directrix of the parabola, the property of which is, that the perpendicular to it, from every point of the curve, is equal to one-fourth of the parameter of the diameter at that point, viz,

PA = $\frac{1}{4}$ the parameter of the diameter at A,
EF = - - - at F,
KD = - - - at D,
LH = - - - at H.

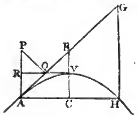
2. If a body, after falling through the height PA, which is equal to AB, and when it arrives at A if its course be changed, by reflection from a firm plane AI, or otherwise, into any direction AC, without altering the velocity; and if AC be taken equal to 2AP or 2AB, and the parallelogram be completed; the body will describe the parabola passing through the point D.

3 Because AC = 2AB or 2CD or 2AP, therefore AC^2 = 2AP . 2CD or AP . 4CD; and because all the perpendiculars EF, CD, GH are as AE^2, AC^2, AG^2; therefore also AP . 4EF = AE^2, and AP . 4GH = AC^2, &c; and because the rectangle of the extremes is equal to the rectangle of the means, of four proportionals, therefore it is always,

and AP : AE : : AE : 4EF,
and AP : AC : : AC : 4CD,
and AP : AG : : AG : 4GH ;
and so on.

IV. Having given the direction of a projectile, and the impetus or altitude due to the first velocity; to determine the greatest height to which it will rise, and the random or horizontal range.

Let AP be the height due to the projectile velocity at A, or the height which a body must fall to acquire the same velocity as the projectile has in the curve at A; also AG the direction, and AH the horizon. Upon AG let fall the perpendicular PQ, and on AP the perpendicular QR; so shall AR be equal to the greatest altitude CV, and 4RQ equal to the horizontal range AH.



Or, having drawn PQ perpendicular to AG, take AG = 4AQ, and draw GH perpendicular to AH; then AH is the range.

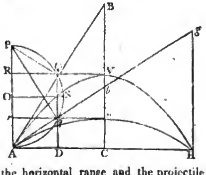
For by the last cor. - - - AP : AG :: AG : 4GH,
and by sim. triangles, - - AP : AG :: AQ : GH,
or AP : AG : : 4AQ : 4GH;

therefore AG = 4AQ; and, by similar triangles, AH = 4RQ.

Also, if V be the vertex of the parabola, then AB or

½AG = 2AQ, or AQ = QB; consequently AR = BV which is = CV by the nature of the parabola.

Hence, 1. Because the angle Q is a right angle, which is the angle in a semicircle, therefore if upon AP as a diameter a semicircle be described, it will pass through the point Q.



2. If the horizontal range and the projectile velocity be given, the direction of the piece so as to strike the object H will be easily found thus: Take AD = ¼AH, and draw DQ perpendicular to AH, meeting the semicircle described on the diameter AP in Q and q; then either AQ or Aq will be the direction of the piece. And hence it appears, that there are two directions AB and Ab which, with the same projectile velocity, give the very same horizontal range AH; and these two directions make equal angles qAD and QAP with AH and AP, because the arc PQ is equal to the arc Aq.

3. Or if the range AH and direction AB be given; to find the altitude and velocity or impetus: Take AD = ¼AH, and erect the perpendicular DQ meeting AB in Q; so shall DQ be equal to the greatest altitude CV. Also erect AP perpendicular to AH, and QP to AQ; so shall AP be the height due to the velocity.

4. When the body is projected with the same velocity, but in different directions; the horizontal ranges AH will be as the sines of double the angles of elevation. Or, which is the same thing, as the rectangle of the sine and cosine of elevation. For AD or RQ, which is ¼AH, is the sine of the arc AQ, which measures double the angle QAD of elevation.

And when the direction is the same, but the velocities different, the horizontal ranges are as the square of the velocities, or as the height AP which is as the square of the velocity; for the sine AD or RQ, or ¼AH, is as the radius, or as the diameter AP.

Therefore, when both are different, the ranges are in the compound ratio of the squares of the velocities, and the sines of double the angles of elevation.

5. The greatest range is when the angle of elevation is half a right angle, or 45°. For the double of 45 is 90°, which has the greatest sine. Or the radius OS, which is ¼ of the range, is the greatest sine.

And hence the greatest range, or that at an elevation of 45°, is just double the altitude AP which is due to the velocity. Or equal to 4VC. And consequently, in that case, C is the focus of the parabola, and AH its parameter. And the ranges are equal at angles equally above and below 45°.

6. When the elevation is 15°, the double of which, or 30°, having its sine equal to half the radius, consequently its range will be equal to AP, or half the greatest range at the elevation of 45°; that is, the range at 15° is equal to the impetus or height due to the projectile velocity.

7. The greatest altitude CV, being equal to AR, is as the versed sine of double the angle of elevation, and also as AP or the square of the velocity. Or as the square of the sine of elevation, and the square of the velocity; for the square of the sine is as the versed sine of the double angle.

8. The time of flight of the projectile, which is equal to the time of a body falling freely through GH or 4CV, 4 times the altitude, is therefore as the square root of the altitude, or as the projectile velocity and sine of the elevation.

9. And hence may be deduced the following set of theorems, for finding all the circumstances relating to projectiles on horizontal planes, having any two of them given. Thus, let

s, c, t = sine, cosine, and tang. of elevation,

S, v = sine and vers. of double the elevation,

R the horizontal range, T the time of flight, V the projectile velocity, H the greatest height of the projectile, $g = 16\frac{1}{12}$ feet, and a = the impetus or the altitude due to the velocity V. Then,

$$R = 2aS = 4asc = \frac{SV^2}{2g} = \frac{scV^2}{g} = \frac{gcT^2}{s} = \frac{gT^2}{t} = \frac{4H}{t}.$$

$$V = \sqrt{4ag} = \sqrt{\frac{2gR}{S}} = \sqrt{\frac{gR}{sc}} = \frac{gT}{s} = \frac{2\sqrt{gH}}{s}.$$

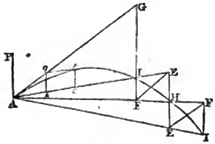
$$T = \frac{sV}{g} = 2s\sqrt{\frac{a}{g}} = \sqrt{\frac{tR}{g}} = \sqrt{\frac{sR}{gc}} = 2\sqrt{\frac{H}{g}}.$$

$$H = as^2 = \tfrac{1}{2}av = \tfrac{1}{4}tR = \frac{sR}{4c} = \frac{sV^2}{4g} = \frac{vV^2}{8g} = \frac{gT^2}{4}.$$

And from any of these, the angle of direction may be found.

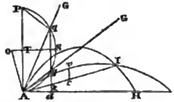
V. To determine the range on an oblique plane; having given the impetus or the velocity, and the angle of direction.

Let AE be the oblique plane, at a given angle above or below the horizontal plane AH; AG the direction of the piece; and AP the altitude due to the projectile velocity at A.



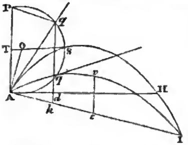
By the last prop. find the horizontal range AH to the given velocity and direction; draw HE perpendicular to AH meeting the oblique plane in E; draw EF parallel to the direction AG, and FI parallel to HE; so shall the projectile pass through I, and the range on the oblique plane will be AI. This is evident from prob. 17 of the parabola in my Treatise on Conic Sections, where it is proved, that if AH, AI be any two lines terminated at the curve, and IF, HE be parallel to the axis; then is EF parallel to the tangent AG.

Hence, 1. If AO be drawn perpendicular to the plane AI, and AP be bisected by the perpendicular STO; then



with the centre O describing a circle through A and P, the same will also pass through q, because the angle GAI, formed by the tangent AO and AI, is equal to the angle APq, which will therefore stand upon the same arc Aq.

2. If there be given the range and velocity, or the impetus, the direction will then be easily found thus: Take Ak $= \frac{1}{4}$AI, draw kq perpendicular to AH, meeting the circle described with the radius AO in two points q and q; then Aq or Aq will be the direction of the piece. And hence it appears that there are two directions, which, with the same impetus, give the very same range AI, on the oblique plane. And these two directions make equal angles with AI and AP, the plane and the perpendicular, because the arc Pq = the arc Aq. They also make equal angles with a line drawn from A through S, because the arc Sq = the arc Sq.



3. Or, if there be given the range AI, and the direction Aq; to find the velocity or impetus. Take Ak $= \frac{1}{4}$AI, and erect kq perpendicular to AH meeting the line of direction in q; then draw qP making the angle AqP = the angle Akq; so shall AP be the impetus, or altitude due to the projectile velocity.

4. The range on an oblique plane, with a given elevation, is directly as the rectangle of the cosine of the direction of the piece above the horizon and the sine of the direction above the oblique plane, and reciprocally as the square of the cosine of the angle of the plane above or below the horizon.

For put s = sin. ∠ qAI or APq,
c = cos. ∠ qAH or sin. PAq,
C = cos. ∠ AIH or sin. Akd or Akq or AqP.
Then, in the tri. APq, - - - $c : s$: : AP : Aq,
and in the tri. Akq, - - - C : c : : Aq : Ak,
therefore by compos. - - - $C^2 : cs$: : AP : Ak $= \frac{1}{4}$AI.

So that the oblique range AI $= \frac{cs}{C^2} \times 4$AP.

Hence the range is the greatest when Ak is the greatest, that is when kq touches the circle in the middle point S, and then the line of direction passes through S, and bisects the angle formed by the oblique plane and the vertex. Also the ranges are equal at equal angles above and below this direction for the maximum.

5. The greatest height cv or kq of the projectile, above the plane, is equal to $\frac{s^2}{C^2} \times$ AP. And therefore it is as the impetus and square of the sine of direction above the plane directly, and square of the cosine of the plane's inclination reciprocally.

For C (sin. AqP) : s (sin. APq) : : AP : Aq,
and C (sin. Akq) : s (sin. kAq) : : Aq : kq,
therefore by comp. $C^2 : s^2$: : AP : kq.

6. The time of flight in the curve AVI is $= \frac{2s}{C}\sqrt{\frac{AP}{g}}$, where $g = 16\frac{1}{12}$ feet. And therefore it is as the velocity and sine of direction above the plane directly, and cosine of the plane's inclination reciprocally. For the time of describing the curve, is equal to the time of falling freely through GI or $4kq$ or $\frac{4s^2}{C^2} \times$ AP. Therefore, the time being as the square root of the distance, $\sqrt{g}$: $\frac{2s}{C}\sqrt{AP}$: : $1''$: $\frac{2s}{C}\sqrt{\frac{AP}{g}}$ the time of flight.

7. From the foregoing corollaries may be collected the following set of theorems, relating to projectiles made on any given inclined planes, either above or below the horizontal plane. In which the letters denote as before, namely,

c = cos. of direction above the horizon,
C = cos. of inclination of the plane,
s = sin. of direction above the plane,
R the range on the oblique plane,
T the time of flight,
V the projectile velocity,
H the greatest height above the plane,
a the impetus, or alt. due to the velocity V,
$g = 16\frac{1}{12}$ feet. Then

$$R = \frac{cs}{C^2} \times 4a = \frac{cs}{C^2 g}V^2 = \frac{gc}{s}T^2 = \frac{4c}{s}H.$$

$$H = \frac{s^2}{C^2}a = \frac{s^2V^2}{4gC^2} = \frac{sR}{4c} = \frac{g}{4}T^2.$$

$$V = \sqrt{4ag} = C\sqrt{\frac{gR}{cs}} = \frac{gC}{s}T = \frac{2C}{s}\sqrt{gH}.$$

$$T = \frac{2s}{C}\sqrt{\frac{a}{g}} = \frac{sV}{gC} = \sqrt{\frac{sR}{gc}} = 2\sqrt{\frac{H}{g}}.$$

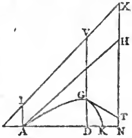
And from any of these, the angle of direction may be found.

Of the Path of PROJECTILES *as depending on the Resistance of the Air.*

For a long time after Galileo, philosophers seemed to be satisfied with the parabolic theory of projectiles, deeming the effect of the air's resistance on the path as of no consequence. In process of time however, as the true philosophy began to dawn, they began to suspect that the resistance of the medium might have some effect on the projectile curve, and they set themselves to consider this subject with some attention.

Huygens, supposing that the resistance of the air was proportional to the velocity of the moving body, concluded that the line described by it would be a kind of logarithmic curve.

But Newton, having clearly proved, that the resistance to the body is not proportional to the velocity itself, but to the square of it, shows, in his Principia, that the line a projectile describes, approaches nearer to an hyperbola than a parabola. Schol. prop. 10, lib. 2. Thus if AGK be a curve of the hyperbolic kind, one of whose asymptotes is NX, perpendicular to the horizon AK, and the other IX inclined to the same, where VG is reciprocally as DN^n, whose index is n: this curve will nearer represent the path of a projectile thrown in the direction AH in the air, than a para-



bola. Newton indeed says, that these hyperbolas are not accurately the curves that a projectile makes in the air; for the true ones are curves which about the vertex are more distant from the asymptotes, and in the parts remote from the axis approach nearer to the asymptotes than these hyperbolas; but that in practice these hyperbolas may be used instead of those more compounded ones. And if a body be projected from A, in the right line AH, and AI be drawn parallel to the asymptote NX, and GT a tangent to the curve at the vertex: Then the density of the medium in A will be reciprocally as the tangent AH, and the body's velocity will be as $\sqrt{\frac{AH^2}{AI}}$, and the resistance of the medium will be to gravity, as

$$AH \text{ to } \frac{2n^2 + 2n}{n + 2} \times AI.$$

John Bernoulli constructed this curve by means of the quadrature of some transcendental curves, at the request of Dr. Keil, who proposed this problem to him in 1718. It was also resolved by Dr. Taylor; and another solution of it may be found in Hermann's Phoronomia.

The commentators Le Sieur and Jacquier say, that the description of the curve in which a projectile moves, is so very perplexed, that it can scarcely be expected any deduction should be made from it, either to philosophical or mechanical purposes: vol. 2, pa. 118.

Dan. Bernoulli too proved, that the resistance of the air has a very great effect on the swift motions, such as those of cannon shot. He concludes from experiment, that a ball which ascended only 7819 feet in the air, would have ascended 58750 feet in vacuo, being near 8 times as high. Comment. Acad. Petr. tom. 2.

Euler has still farther investigated the nature of this curve, and directed the calculation and use of a number of tables for the solution of all cases that occur in gunnery, which may be accomplished with nearly as much expedition as by the common parabolic principles. Memoirs of the Academy of Berlin, for the year 1753.

But how rash and erroneous the old opinion of the inconsiderable resistance of the air is, will easily appear from the experiments of Mr. Robins, who has shown that, in some cases, this resistance to a cannon ball, amounts to more than 20 times the weight of the ball; and I myself, having prosecuted this subject far beyond any former example, have sometimes found this resistance amount to near 100 times the weight of the ball, viz, when it moved with a velocity of 2000 feet per second, which is a rate of almost 23 miles in a minute. What errors then may not be expected from an hypothesis which neglects this force, as inconsiderable? Indeed it is easy to show, that the path of such projectiles is neither a parabola nor nearly a parabola. For, by that theory, if the ball, in the instance last mentioned, moved in the curve of a parabola, its horizontal range, at 45° elevation, will be found to be almost 24 miles; whereas it often happens that the ball, with such a velocity, ranges far short of even one mile.

Indeed the fallacy of this hypothesis almost appears at sight, even in projectiles slow enough to have their motion traced by the eye; for they are seen to descend through a curve manifestly shorter and more inclined to the horizon than that in which they ascended, and the highest point of their flight, or the vertex of the curve, is much nearer to the place where they fall on the ground, than to that from which they were at first discharged. These things cannot for a moment be doubted of by any one, who in a proper situation views the flight of stones arrows, or shells, thrown to any considerable distance.

Mr. Robins has not only detected the errors of the parabolic theory of gunnery, which takes no account of the resistance of the air, but attempts to show how to compute the real range of resisted bodies. But for the method which he proposes, and the tables he has computed for this purpose, see his Tracts of Gunnery, pa. 183, &c, vol. 1; and also Euler's Commentary on the same, translated by Mr. Hugh Brown, in 1777.

There is an odd circumstance which often takes place in the motion of bodies projected with considerable force, which shows the great complication and difficulty of this subject; namely, that bullets in their flight are not only depressed beneath their original direction by the action of gravity, but are also frequently driven to the right or left of that direction by the action of some other force. Now if it were true that bullets varied their direction by the action of gravity only, then it ought to happen that the errors in their flight to the right or left of the mark they were aimed at, should increase in the proportion of the distance of the mark from the piece only. But this is contrary to all experience; the same piece which will carry its bullet within an inch of the intended mark, at 10 yards distance, cannot be relied on to 10 inches in 100 yards, much less to 30 in 300 yards.

And this inequality can only arise from the track of the bullet being incurvated sideways as well as downwards; for by this means the distance between the incurvated line and the line of direction, will increase in a much greater ratio than that of the distance; these lines coinciding at the mouth of the piece, and afterwards separating in the manner of a curve from its tangent, if the mouth of the piece be considered as the point of contact.

This is put beyond a doubt from the experiments made by Mr. Robins; who found also that the direction of the shot in the perpendicular line was not less uncertain, falling sometimes 200 yards short of what it did at other times, though there was no visible cause of difference in making the experiment. And I myself have often experienced a difference of one-fifth or one-sixth of the whole range, both in the deflection to the right or left, and also in the extent of the range, of cannon shot.

If it be asked, what can be the cause of a motion so different from what has been hitherto supposed? It may be answered, that the deflection in question must be owing to some power acting obliquely to the progressive motion of the body, which power can be no other than the resistance of the air. And this resistance may perhaps act obliquely to the progressive motion of the body, from inequalities in the resisted surface; but its general cause is doubtless a whirling motion acquired by the bullet about an axis, by its friction against the sides of the piece; for by this motion of rotation, combined with the progressive motion, each part of the ball's surface will strike the air in a direction very different from what it would do if there was no such whirl; and the obliquity of the action of the air, arising from this cause, will be greater, according as the rotatory motion of the bullet is greater in proportion to its progressive motion. Tracts, vol. 3.

M. Euler, on the contrary, attributes this deflection of the ball to its figure, and very little to its rotation: for if the ball was perfectly round, though its centre of gravity did not coincide with the centre of spontaneous rotation, the deflection from the axis of the cylinder, or line of direction sideways, would be very inconsiderable. but when it is not round, it will generally go to the right or left of its direction, and so much the more, as its range is greater. From his reasoning on this subject he infers, that cannon shot, which are made of iron, and rounder and less susceptible of a change of figure in passing along the cylinder than those of lead, are more certain than musket shot. True Principles of Gunnery investigated, 1777, pa. 304, &c. And for the experiments on the air's resistance to all balls and velocities, with the application to gunnery, see my Tracts, vols. 2 and 3.

PROJECTION, in Mechanics, the act of giving a projectile its motion.—If the direction of the force, by which the projectile is put in motion, be perpendicular to the horizon, the projection is said to be perpendicular; if parallel to the apparent horizon, it is said to be an horizontal projection; and if it make an oblique angle with the horizon, the projection is oblique. In all cases the angle which the line of direction makes with the horizontal line, is called the angle of elevation of the projectile, or of depression when the line of direction points below the horizontal line.

Projection, in Perspective, denotes the appearance or representation of an object on the perspective plane. So, the projection of a point, is a point, where the optic ray passes from the objective point through the plane to the eye; or it is the point where the plane cuts the optic ray. And hence it is easy to conceive what is meant by the projection of a line, a plane, or a solid.

Projection *of the Sphere in Plano*, is a representation of the several points or places of the surface of the sphere, and of the circles described upon it, on a supposed transparent plane placed between the eye and the sphere, or such as they appear to the eye placed at a given distance. For the laws of this projection, see Perspective: the projection of the sphere being only a particular case of perspective.—The chief use of the projection of the sphere, is in the construction of planispheres, maps, and charts; which are said to be of this or that projection, according to the several situations of the eye, and the perspective plane, with regard to the meridians, parallels, and other points or places to be represented.—The most usual projection of maps of the world, is that on the plane of the meridian, which exhibits a right sphere; the first meridian being the horizon. The next is that on the plane of the equator, which has the pole in the centre, and the meridians the radii of a circle, &c; which represents a parallel sphere. See Map.

The projection of the sphere is usually divided into orthographic and stereographic; to which may be added gnomonic.

Orthographic Projection, is that in which the surface of the sphere is drawn upon a plane, cutting it in the middle; the eye being placed at an infinite distance vertically to one of the hemispheres. And

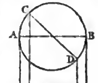
Stereographic Projection of the sphere, is that in which the surface and circles of the sphere are drawn upon the plane of a great circle, the eye being in the pole of that circle.

Gnomonical Projection *of the Sphere*, is that in which the surface of the sphere is drawn upon a plane without side of it, commonly touching it, the eye being at the centre of the sphere. See Gnomonical *Projection*.

Laws of the Orthographic Projection.

1. The rays coming from the eye, being at an infinite distance, and making the projection, are parallel to each other, and perpendicular to the plane of projection.

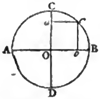
2. A right line perpendicular to the plane of projection, is projected into a point, where that line meets the said plane.



3. A right line, as AB, or CD, not perpendicular, but either parallel or oblique to the plane of the projection, is projected into a right line, as EF or GH, and is always comprehended between the extreme perpendiculars AE and BF, or CG and DH.

4. The projection of the line AB is the greatest, when AB is parallel to the plane of the projection.

5. Hence it is evident, that a line parallel to the plane of projection, is projected into a right line equal to itself; but a line that is oblique to the plane of projection, is projected into one that is less than itself.



6. A plane surface, as ACBD, perpendicular to the plane of projection, is projected into the right line, as AB, in which it cuts that plane.—Hence it is evident, that the circle ACBD perpendicular to the plane of projection, passing through its centre, is projected into that diameter AB in which it cuts the plane of the projection. Also any arch as cc is projected into oo, equal to *ca*, the right sine of that arch; and the complemental arc CB is projected into OB, the versed sine of the same arc CB.

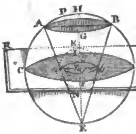
7. A circle parallel to the plane of projection, is projected into a circle equal to itself, having its centre the same with the centre of the projection, and its radius equal to the cosine of its distance from the plane. And a circle oblique to the plane of projection, is projected into an ellipsis, whose greater axis is equal to the diameter of the circle, and its less axis equal to double the cosine of the obliquity of the circle, to a radius equal to half the greater axis.

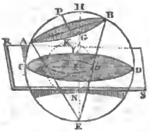
Properties of the Stereographic Projection.

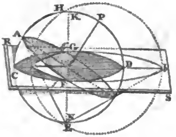
1. In this projection a right circle, or one perpendicular to the plane of projection, and passing through the eye, is projected into a line of half tangents.

2. The projection of all other circles, not passing through the projecting point, whether parallel or oblique, are projected into circles.

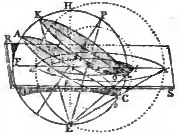
Thus, let ACEDB represent a sphere, cut by a plane RS, passing through the centre I, perpendicular to the diameter EH, drawn from E the place of the eye; and let the section of the sphere by the plane RS be the circle CFDL, whole poles are H and E. Suppose now AGB a circle on the sphere to be projected, whose pole most remote from the eye is P; and the visual rays from the circle AGB meeting in E, to form the cone AGBE, of which the triangle AEB is a section through the vertex E, and diameter of the base AB: then will the figure *aghf*, which is the projection of the circle AGB, be itself a circle. Hence, the middle of the projected diameter is the centre of the projected circle, whether it be a great circle or a small one: Also the poles and centres of all circles, parallel to the plane of projection, fall in the centre of the projection: And all oblique great circles cut the primitive circle in two points diametrically opposite.



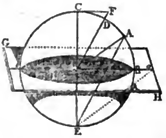




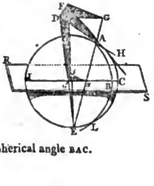
2. The projected diameter of any circle subtends an angle at the eye equal to the distance of that circle from its nearest pole, taken on the sphere; and that angle is bisected by a right line joining the eye and that pole. Thus, let the plane RS cut the sphere HFEG through its centre I; and let ABC be any oblique great circle, whose diameter AC is projected into *ac*; and KOL any small circle parallel to ABC, whose diameter KL is projected in *kl*. Then the distances of those circles from their pole P, being the arcs AHP, KHP; and the angles *a*E*c*, *k*E*l*, being the angles at the eye, subtended by their projected diameters, *ac* and *kl*. It follows that the angle *a*E*c* is measured by the arc AHP, and that the angle *k*E*l* is measured by the arc KHP; and these angles are bisected by EP.



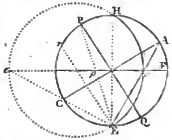
3. Any point of a sphere is projected at such a distance from the centre of projection, as is equal to the tangent of half the arc intercepted between that point and the pole opposite to the eye, the semidiameter of the sphere being radius. Thus, let *cb*EB be a great circle of the sphere, whose centre is *c*, GH the plane of projection, cutting the diameter of the sphere in *b* and B; also E and C the poles of the section by that plane; and *a* the projection of A. Then *ca* is equal the tangent of half the arc AC, as is evident by drawing CF equal to the tangent of half that arc, and joining *c*F.



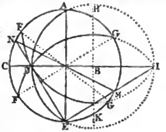
4. The angle made by two projected circles, is equal to the angle which these circles make on the sphere. For let IACE and ABL be two circles on a sphere intersecting in A; E the projecting point; and RS the plane of projection, in which the point A is projected in *a*, in the line IC, the diameter of the circle ACE. Also let DH and FA be tangents to the circles ACE and ABL. Then will the projected angle *daf* be equal to the spherical angle BAC.



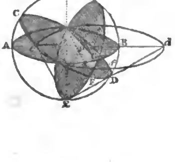
5. The distance between the poles of the primitive circle and an oblique circle, is equal to the tangent of half the inclination of those circles; and the distance of their centres, is equal to the tangent of their inclination; the semidiameter of the primitive circle being radius. For let AC be the diameter of a circle, whose poles are P and Q, and inclined to the plane of projection in the angle AIF; and let *a*, *c*, *p* be the projections of the points A, C, P; also let H*a*E be the projected oblique circle, whose centre is *q*. Now when the plane of projection becomes the primitive circle, whose pole is I; then is I*p* equal to the tangent of half the angle AIF, or of half the arch AF; and I*q* is equal to the tangent of AF, or of the angle FH*a* = AIF.



6. If through any given point in the primitive circle, an oblique circle be described; then the centres of all other oblique circles passing through that point, will be in a right line drawn through the centre of the first oblique circle, and perpendicular to a line passing through that centre, the given point, and the centre of the primitive circle. Thus, let GACE be the primitive circle, ADEI a great circle described through D, its centre being B. HK is a right line drawn through B perpendicular to a right line CI passing through D and B and the centre of the primitive circle. Then the centres of all other great circles, as FDG, passing through D, will fall in the line HK.



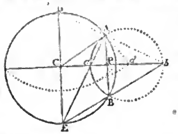
7. Equal arcs of any two great circles of the sphere will be intercepted between two other circles drawn on the sphere through the remotest poles of those great circles. For let PBEA be a sphere, on which AGB and CFD are two great circles, whose remotest poles are E and P; and through these poles let the great circle PBEC and the small circle POE be drawn, cutting the great cir-



cles AGB and CFD in the points B, G, D, F. Then are the intercepted arcs BG and DF equal to each other.

8. If lines be drawn from the projected pole of any great circle, cutting the peripheries of the projected circle and plane of projection; the intercepted arcs of those peripheries are equal; that is, the arc BG = *df*.

9. The radius of any lesser circle, whose plane is perpendicular to that of the primitive circle, is equal to the tangent of that lesser circle's distance from its pole; and the secant of that distance is equal to the distance of the centres of the primitive and lesser circle. For let P be the pole, and AB the diameter of a lesser circle, its plane being perpendicular to that of the primitive circle, whose centre is C: then *d* being the centre of the projected lesser circle, *da* is equal to the tangent of the arc PA, and *dc* = the secant of PA. See STEREOGRAPHIC *Projection*.



Mercator's PROJECTION. See MERCATOR, and CHART.

PROJECTION of Globes, &c. SEE GLOBE, &c.

Polar PROJECTION. See POLAR.

PROJECTION *of Shadows*. See SHADOW.

PROJECTION, or PROJECTURE, in Building, the outjetting or prominency which the mouldings and members have, beyond the plane or naked of the wall, column, &c.

Monstrous PROJECTION. See ANAMORPHOSIS.

PROJECTIVE *Dialling*, a manner of drawing the hour lines, the furniture &c of dials, by a method of projection on any kind of surface whatever, without regard to the situation of those surfaces, either as to declination, reclination, or inclination. See DIALLING.

PROLATE, or OBLONG *Spheroid*, is a spheroid produced by the revolution of a semiellipsis about its longer diameter; being longest in the direction of that axis, and resembling an egg, or a lemon. It is so called in opposition to the oblate or short spheroid, which is formed by the rotation of a semiellipsis about its shorter axis; being therefore shortest in the direction of its axis, or flatted at the poles, and so resembling an orange, or perhaps a turnip, according to the degree of flatness; and which is also the figure of the earth. See SPHEROID.

PROMONTORY, in Geography, is a rock or high point of land projecting out into the sea. The extremity of which towards the sea is usually called a Cape, or Headland.

PROPORTION, in Arithmetic, &c, the equality or similitude of ratios. As the four numbers 4, 8, 15, 30 are proportionals, or in proportion, because the ratio of 4 to 8 is equal or similar to the ratio of 15 to 30, both of them being the same as the ratio of 1 to 2.

Euclid in the 5th definition of the 5th book, gives a general definition of four proportionals, or when, of four terms, the first has the same ratio to the 2d, as the 3d has to the 4th, viz. when any equimultiples whatever of the first and third being taken, and any equimultiples whatever of the 2d and 4th; if the multiple of the first be less than that of the 2d, the multiple of the 3d is also less than that of the 4th; or if the multiple of the first be equal to that of the 2d, the multiple of the 3d is also equal to that of the 4th; or if the multiple of the first be greater than that of the 2d, the multiple of the 3d is also greater than that of the 4th. And this definition is general for all kinds of magnitudes or quantities whatever, though a very obscure one.

Also, in the 7th book, Euclid gives another definition of proportionals, viz, when the first is the same equimultiple of the 2d, as the 3d is of the 4th, or the same part or parts of it. But this definition appertains only to numbers and commensurable quantities.

Proportion is often confounded with ratio; but they are quite different things. For, ratio is properly the relation of two magnitudes or quantities of one and the same kind; as the ratio of 4 to 8, or of 15 to 30, or of 1 to 2; and so implies or respects only two terms or things. But proportion respects four terms or things, or two ratios which have each two terms. Though the middle term may be common to both ratios, and then the proportion is expressed by three terms only, as 4, 8, 64, where 4 is to 8 as 8 to 64.

Proportion is also sometimes confounded with progression. In fact, the two often coincide; the difference between them only consisting in this, that progression is a particular species of proportion, being indeed a continued proportion, or such as has all the terms in the same ratio, viz, the 1st to the 2d, the 2d to the 3d, the 3d to the 4th, &c; as the terms 2, 4, 8, 16, &c; so that progression is a series or continuation of proportions.

Proportion is either continual, or discrete or interrupted.

The proportion is continual when every two adjacent terms have the same ratio, or when the consequent of each ratio is the antecedent of the next following ratio, and so all the terms form a progression; as 2, 4, 8, 16, &c; where 2 is to 4 as 4 to 8, and as 8 to 16, &c.

Discrete or interrupted proportion, is when the consequent of the first ratio is different from the antecedent of the 2d, &c; as 2, 4, and 3, 6.

Proportion is also either direct or inverse.

Direct PROPORTION is when more requires more, or less requires less. As it will require more men to perform more work, or fewer men for less work, in the same time.

Inverse or *Reciprocal* PROPORTION, is when more requires less, or less requires more. As it will require more men to perform the same work in less time, or fewer men in more time. Ex. If 6 men can perform a piece of work in 15 days, how many men can do the same in 10 days.

Then, reciprocally - as $\frac{1}{15}$ to $\frac{1}{10}$ so is 6 : 9 } the
or inversely - as 10 to 15 so is 6 : 9 } answer.

Proportion, again, is distinguished into arithmetical, geometrical, and harmonical.

Arithmetical PROPORTION is the equality of two arithmetical ratios, or differences. As in the numbers 12, 9, 6; where the difference between 12 and 9, is the same as the difference between 9 and 6, viz 3. And here the sum of the extreme terms is equal to the sum of the means, or to double the single mean when there is but one. As $12 + 6 = 9 + 9 = 18$.

Geometrical PROPORTION is the equality between two geometrical ratios, or between the quotients of the terms. As in the three 9, 6, 4, where 9 is to 6 as 6 is to 4, thus denoted, 9 : 6 : : 6 : 4; for $\frac{9}{6} = \frac{6}{4}$, being each equal $\frac{3}{2}$ or $1\frac{1}{2}$. And in this proportion, the rectangle or product of the extreme terms, is equal to that of the two means, or the square of the single mean when there is but one. For $9 \times 4 = 6 \times 6 = 36$.

Harmonical PROPORTION, is when the first term is to the third, as the difference between the 1st and 2d is to the difference between the 2d and 3d; or, in four terms, when the 1st is to the 4th, as the difference between the 1st and 2d is to the difference between the 3d and 4th; or the reciprocals of an arithmetical proportion are in harmonical proportion. As 6, 4, 3; because $6 : 3 :: 6 - 4 = 2 : 4 - 3 = 1$; or because $\frac{1}{6}, \frac{1}{4}, \frac{1}{3}$, are in arithmetical proportion, making $\frac{1}{6} + \frac{1}{3} = \frac{1}{4} + \frac{1}{4} = \frac{1}{2}$. Also the four 24, 16, 12, 9 are in harmonical proportion, because $24 : 9 :: 8 : 3$.

See PROPORTIONALS.

Compass of PROPORTION, a name by which the French, and some English authors, call the Sector.

Rule of PROPORTION, in Arithmetic, a rule by which a 4th term is found in proportion to three given terms. It is popularly called the Golden Rule, or Rule of Three.

PROPORTIONAL, relating to proportion. As, Proportional Compasses, Parts, Scales, Spirals, &c. See the several terms.

PROPORTIONAL *Compasses*, are compasses with two pair of opposite legs, like a St. Andrew's cross, by which any space is enlarged or diminished in any proportion.

PROPORTIONAL *Part*, is a part of some number that is analogous to some other part or number; such as the proportional parts in the logarithms, and other tables.

PROPORTIONAL *Scales*, called also logarithmic scales, are the logarithms, or artificial numbers, placed on lines, for the ease and advantage of multiplying and dividing &c, by means of compasses, or of sliding rulers. These are in effect so many lines of numbers, as they are called by Gunter, but made single, double, triple, or quadruple; beyond which they seldom go. See GUNTER'S *Scale*, SCALE, &c.

PROPORTIONAL *Spiral*. See SPIRAL.

PROPORTIONALITY, the quality of proportionals. This term is used by Gregory St. Vincent, for the proportion between the exponents of four ratios.

PROPORTIONALS, are the terms of a proportion; consisting of two extremes, which are the first and last terms of the set, and the means, which are the other terms. These proportionals may be either arithmeticals, geometricals, or harmonicals, and in any number above two, and also either continued or discontinued.

Pappus gives this beautiful and simple comparison of the three kinds of proportionals, arithmetical, geometrical, and harmonical, viz. a, b, c, being the first, second, and third terms in any such proportion, then

$$\left.\begin{array}{ll}\text{In the arithmeticals,} & a : a \\ \text{in the geometricals,} & a : b \\ \text{in the harmonicals,} & a : c\end{array}\right\} :: a - b : b - c.$$

See MEAN *Proportional*.

Continued proportionals form what is called a progression; for the properties of which see PROGRESSION.

I. *Properties of Arithmetical* PROPORTIONALS.

(For what respects progressions and mean proportionals of all sorts, see MEAN, and PROGRESSION).

1. Four arithmetical proportionals, as 2, 3, 4, 5, are still proportionals taken inversely, as 5, 4, 3, 2; or alternately, thus, 2, 4, 3, 5; or inversely and alternately, thus 5, 3, 4, 2.

2. If two arithmeticals be added to the like terms of other two arithmeticals, of the same difference, or arithmetical ratio, the sums will have double the same difference or arithmetical ratio.

So, to 3 and 5, whose difference is 2,
add 7 and 9, whose difference is also 2,
the sums 10 and 14 have a double diff. viz, 4.

And if to these sums be added two other numbers also in the same difference, the next sums will have a triple ratio or difference; and so on. Also, whatever be the ratios of the terms that are added, whether the same or different, the sums of the terms will have such arithmetical ratio as is composed of the sums of the others that are added.

So	3 ,	5, whose dif. is	2
and	7 ,	10, whose dif. is	3
and	12 ,	16, whose dif. is	4
make	22 ,	31, whose dif. is	9.

On the contrary, if from two arithmeticals there be subtracted others, the difference will have such arithmetical ratio as is equal to the differences of those.

So from	12 and 16, whose dif. is	4
take	7 and 10, whose dif. is	3
leaves	5 and 6, whose dif. is	1
Also from	7 and 9, whose dif. is	2
take	3 and 5, whose dif. is	2
leaves	4 and 4, whose dif. is	0

3. Hence, if arithmetical proportionals be multiplied or divided by the same number, their difference, or arithmetical ratio, is also multiplied or divided by the same number.

II. *Properties of Geometrical Proportionals.*

The properties relating to mean proportionals are given under the term MEAN *Proportional*; some are also given under the article PROPORTION; and some additional ones are as below:

1. To find a 3d proportional to two given numbers, or a 4th proportional to three: In the former case, multiply the 2d term by itself, and divide the product by the 1st: and in the latter case, multiply the 2d term by the 3d, and divide the product by the 1st.

So $2 : 6 :: 6 : 18$, the 3d prop. to 2 and 6:
and $2 : 6 :: 5 : 15$, the 4th prop. to 2, 6, and 5.

2. If the terms of any geometrical ratio be augmented or diminished by any others in the same ratio, or proportion, the sums or differences will still be in the same ratio or proportion.

So if $a : b :: c : d$,
then is $a : b :: a \pm c : b \pm d :: c : d$.

And if the terms of a ratio, or proportion, be multiplied or divided by the same number, the products and quotients will still be in the same ratio, or proportion.

Thus, $a : b :: na : nb :: \frac{a}{n} : \frac{b}{n}$.

3. If a set of continued proportionals be either augmented or diminished by the same part or parts of themselves, the sums or differences will also be proportionals.

Thus if a, b, c, d, &c be propors.
then are $a \pm \frac{a}{n}$, $b \pm \frac{b}{n}$, $c \pm \frac{c}{n}$, &c also propors.
where the common ratio is $1 \pm \frac{1}{n}$.

And if any single quantity be either augmented or diminished by some part of itself, and the result be also increased or diminished by the same part of itself, and this third quantity treated in the same manner, and so on; then shall all these quantities be continued proportionals. So, beginning with the quantity a, and taking always the nth part, then shall

$a,\ a \pm \frac{a}{n},\ a \pm \frac{2a}{n} + \frac{a^2}{n^2}$, &c be proportionals,

or $a,\ a \pm \frac{a}{n},\ (a \pm \frac{a}{n})^2,\ (a \pm \frac{a}{n})^3$, &c propors.

the common ratio being $1 \pm \frac{a}{n}$.

4. If one set of proportionals be multiplied or divided by any other set of proportionals, each term by each, the products or quotients will also be proportionals.

Thus, if $a : na :: b : nb$,
and $c : mc :: d : md$;
then is $ac : mnac :: bd : mnbd$,
and $\frac{a}{c} : \frac{na}{mc} :: \frac{b}{d} : \frac{nb}{mb}$.

5. If there be several continued proportionals, then whatever ratio the 1st has to the 2d, the first to the 3d shall have the duplicate of the ratio, the 1st to the 4th the triplicate of it, and so on.

So in a, na, n^2a, n^3a, &c, the ratio being n;
then $a : n^2a$, or 1 to n^2, the duplicate ratio,
and $a : n^3a$, or 1 to n^3, the triplicate ratio, &c.

6. In three continued proportionals, the difference between the 1st and 2d term, is a mean proportional between the 1st term and the 2d difference of all the terms.

Thus, in the three propor. a, na, n^2a;

Terms	1st difs.	2d dif.
n^2a		
na	$n^2a - na$	$n^2a - 2na + a$,
a	$na - a$	

then $a : na - a :: na - a : n^2a - 2na + a$.

Or in the numbers 2, 6, 18;

18		
6	12	8 the 2d difference;
2	4	

then 2, 4, 8 are proportionals.

7. When four quantities are in proportion, they are also in proportion by inversion, composition, division, &c; thus a, na, b, nb being in proportion, viz.

1.	$a : na :: b : nb$;	then by
2. Inversion	$na : a :: nb : b$;	
3. Alternation	$a : b :: na : nb$;	
4. Composition	$a + na : na :: b + nb : nb$;	
5. Conversion	$a + na : a :: b + nb : b$;	
6. Division	$a - na : a :: b - nb : b$;	
	$a - na : na :: b - nb : nb$.	

III. *Properties of Harmonical Proportionals.*

1. If three or four numbers in harmonical proportion, be either multiplied or divided by any number, the products or quotients will also be harmonical proportionals.

Thus, 6, 3, 2 being harmon. propor.
then 12, 6, 4 are also harmon. propor.
and $\frac{6}{2}, \frac{3}{2}, \frac{2}{2}$ are also harmon. propor.

2. In the three harmonical proportionals a, b, c, when any two of these are given, the 3d can be found from the definition of them, viz, that $a : c :: a - b : b - c$; for hence

$b = \frac{2ac}{a + c}$ the harmonical mean, and

$c = \frac{ab}{2a - b}$ the 3d harmon. to a and b.

3. And of the four harmonicals, a, b, c, d, any three being given, the fourth can be found from the definition of them, viz, that $a : d :: a - b : c - d$; for thence the three b, c, d, will be thus found, viz,

$$b = \frac{2ad - ac}{d};\ c = \frac{2ad - bd}{a};\ d = \frac{ac}{2a - b}.$$

4. If there be four numbers disposed in order, as 2, 3, 4, 6, of which one extreme and the two middle terms are in arithmetical proportion, and the other extreme and the same middle terms are in harmonical proportion; then are the four terms in geometrical proportion: thus,

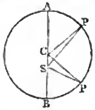
the three 2, 3, 4 are arithmeticals,
and the three 3, 4, 6 are harmonicals,
then the four 2, 3, 4, 6 are geometricals.

5. If between any two numbers, as 2 and 6, there be interposed an arithmetical mean 4, and also a harmonical mean 3, the four will then be geometricals, viz, 2 : 3 :: 4 : 6.

6. Between the three kinds of proportion, there is this remarkable difference; viz, that from any given number there can be raised a continued arithmetical series increasing ad infinitum, but not decreasing; while the harmonical can be decreased ad infinitum, but not increased; and the geometrical admits of both.

PROPOSITION, is either some truth advanced, and shown to be such by demonstration; or some operation proposed, and its solution shown. In short, it is something proposed either to be demonstrated, or to be done or performed. The former is a theorem, and the latter is a problem.

PROSTHAPHERESIS, in Astronomy, the difference between the true and mean motion, or between the true and mean place, of a planet, or between the true and equated anomaly; called also equation of the orbit, or equation of the centre, or simply the equation; and it is equal to the angle formed at the planet, and subtended by the excentricity of its orbit. Thus, if S be the sun, and P the place of a planet in its orbit APB, whose centre is C. Then the



Mean anomaly is the ∠ ACP,
true anomaly is the ∠ ASP,
dif. of which is the ∠ CPS,
which is the prosthapheresis; which is so called, because it is sometimes to be added to, and sometimes to be subtracted from the mean motion, to give the true one; as is evident from the figure.

PROTRACTING, or PROTRACTION, in Surveying, the act of plotting or laying down the dimensions taken in the field, by means of a Protractor, &c: Protracting makes one part of surveying.

PROTRACTING-*Pin*, a fine pointed pin, or needle, fitted into a handle, used to prick off degrees and minutes from the limb of the protractor.

PROTRACTOR, a mathematical instrument, used in surveying, for laying down angles on paper, &c.

The simplest, and most natural protractor consists of a semicircular limb ADB (fig. 7, plate 24) commonly of metal, divided into 180°, and subtended by a diameter AB; in the middle of which is a small notch C, called the centre of the protractor. And for the convenience of reckoning both ways, the degrees are numbered from the left hand towards the right, and from the right hand towards the left.

But this instrument is made much more commodious by transferring the divisions from the circumference to the edge of a ruler, whose side EF is parallel to AB, which is easily done by laying a ruler on the centre C, and over the several divisions on the semicircumference ADB, and marking the intersections of that ruler on the line EF; so that a ruler with these divisions marked on one of its sides as above, and returned down the two ends, and numbered both ways as in the circular protractor, the fourth or blank side representing the diameter of the circle, is both a more useful form than the circular protractor, and better adapted for putting into a case.

To make any Angle with the Protractor.—Lay the diameter of the protractor along the given line, which is to be one side of the angle, and its centre at the given angular point; then make a mark opposite the given degree of the angle found on the limb of the instrument, and, removing the protractor, by a plane ruler laid over that point and the centre, draw a line, which will form the angle sought. In the same way is any given angle measured, to find the number of degrees it contains.—This protractor is also very useful in drawing one line perpendicular to another, which is readily done by laying the protractor across the given line, so that both its centre and the 90th degree on the opposite edge fall upon the line, also one of the edges passing over the given point, by which then let the perpendicular be drawn.

The Improved PROTRACTOR is an instrument much like the former, only furnished with a little more apparatus, by which an angle may be set off to a minute.

The chief addition is an index attached to the centre, about which it is moveable, so as to play freely and steadily over the limb: beyond this limb the index is divided, on both edges, into 60 equal parts of the portions of circles, intercepted by two other right lines drawn from the centre, so that each makes an angle of 1° with lines drawn to the assumed points from the centre.

To set off an angle of any number of degrees and minutes with this protractor, move the index, so that one of the lines drawn on the limb, from one of the fore-mentioned points, may fall upon the number of degrees given; and prick off as many of the equal parts on the proper edge of the index as there are minutes given; then drawing a line from the centre to that point so pricked off, the required angle is thus formed with the given line or diameter of the protractor.

The best protractors are now made with a vernier, and fine pins, to prick off angles to minutes.

PROVING *of Gunpowder*. See EPROUVETTE, and GUNPOWDER.

PSEUDO-STELLA, any kind of meteor or phenomenon, appearing in the heavens, and resembling a star.

PTOLEMAIC, or PTOLOMAIC, something relating to Ptolemy; as the Ptolemaic System, the Ptolemaic Sphere, &c. See SYSTEM, SPHERE, &c.

PTOLEMY, or PTOLOMY, (CLAUDIUS), a celebrated geographer, astronomer, and mathematician, was born at Pelusium in Egypt, about the 70th year of the Christian era; and died, it has been said, in the 78th year of his age, and in the year of Christ 147. He taught astronomy at Alexandria in Egypt, where he made many astronomical observations, and composed his other works. It is certain however that he flourished in the reigns of Marcus Antoninus and Adrian: for it is noted in his canon, that Antoninus Pius reigned 23 years, which shows that he himself survived him; he also tells us in one place, that he made a great many observations on the fixed stars at Alexandria, in the second year of Antoninus Pius; and in another, that he observed an eclipse of the moon, in the 9th year of Adrian; from which it is reasonable to conclude that this astronomer's observations on the heavens were many of them made between the years 125 and 140.

Ptolemy has always been reckoned the prince of astronomers among the ancients, and in his works has left us an entire body of that science. He has preserved and transmitted to us the observations and principal discoveries of the ancients, and at the same time augmented and enriched them with his own. He corrected Hipparchus's catalogue of the fixed stars; and formed tables, by which the motions of the sun, moon, and planets, might be calculated and regulated. He was indeed the first who collected the scattered and detached observations of the ancients, and digested them into a system; which he set forth in his Μεγαλη Συνταξις, sive Magna Constructio, divided into 13 books. He there adopts and exhibits the ancient system of the world, which placed the earth in the centre of the universe; and this has been called after him the Ptolemaic System, to distinguish it from those of Copernicus and Tycho Brahé.

About the year 827 this work was translated by the Arabians into their language, in which it was called Almagestum, by order of one of their kings; and from Arabic into Latin, about 1230, by the encouragement of the emperor Frederic the 2d. There were also other versions from the Arabic into Latin; and a manuscript of one, done by Girardus Cremonensis, who flourished about the middle of the 14th century, which, Fabricius says, is still extant in the library of All Souls College in Oxford. The Greek text of this work began to be read in Europe in the 15th century; and was first published by Simon Grynæus at Basil, 1538, in folio, with the eleven books of commentaries by Theon, who flourished at Alexandria in the reign of the elder Theodosius. In 1541 it was reprinted at Basil, with a Latin version by George Trapezond; and again at the same place in 1551, with the addition of other works of Ptolemy, and Latin versions by Camerarius: which last edition, we learn from Kepler, was used by Tycho.

Of this principal work of the ancient astronomers, it may not be improper to give here a more particular account. In general, it may be observed, that it is founded on the hypothesis of the earth's being at rest in the centre of the universe, and that the heavenly bodies, the stars and planets, all move around it in solid orbs, whose motions are all directed by one, which Ptolemy called the primum mobile, or first mover, of which he discourses at large. The whole of this great work is divided into 13 books.

In the first book, Ptolemy shows, that the earth is in the centre of those orbs, and of the universe itself, as he understood it: he represents the earth as of a spherical figure, and but as a point in comparison of the rest of the heavenly bodies: he then treats of the several circles of the earth, and their distances from the equator; as also of the right and oblique ascension of the heavenly bodies in a right sphere.

In the 2d book, he treats of the habitable parts of the earth; of the elevation of the pole in an oblique sphere, and the various angles which the several circles make with the horizon, according to the different latitude of places; also of the phenomena of the heavenly bodies depending on the same.

In the 3d book, he treats of the quantity of the year, and of the unequal motion of the sun through the zodiac:

and he here also gives the method of computing the mean motion of the sun, with tables of the same; and also treats of the inequality of days and nights.

In the 4th book, he treats of the lunar motions, and their various phenomena: and gives tables for finding the moon's mean motions, with her latitude and longitude: he discourses largely concerning lunar epicycles; and by comparing the times of a great number of eclipses, mentioned by Hipparchus, Calippus, and others, he has computed the places of the sun and moon, according to their mean motions, from the first year of Nabonazar, king of Egypt, to his own time.

In the 5th book, he treats of the instrument called the astrolabe, and also of the excentricity of the lunar orbit, and the inequality of the moon's motion, according to her distance from the sun: he also gives tables, and a universal canon for the inequality of the lunar motions: he then treats of the different aspects or phases of the moon, and gives a computation of the diameter of the sun and moon, with the magnitude of the sun, moon and earth compared together; he states also the different measures of the distance of the sun and moon, according as they are determined by ancient mathematicians and philosophers.

In the 6th book, he treats of the conjunctions and oppositions of the sun and moon, with tables for computing the mean time when they happen; of the boundaries of solar and lunar eclipses; of the tables and methods of computing the eclipses of the sun and moon, with many other particulars.

In the 7th book, he speaks of the fixed stars; and shows the methods of describing them, in their various constellations, on the surface of an artificial sphere or globe: he rectifies the places of the stars to his own time, and shows how different those places were then, from what they had been in the times of Timocharis, Hipparchus, Aristillus, Calippus, and others: he then lays down a catalogue of the stars in each of the northern constellations, with their latitude, longitude, and magnitudes.

In the 8th book, he gives a like catalogue of the stars in the constellations of the southern hemisphere, and in the 12 signs or constellations of the zodiac. This is the oldest catalogue of the stars now extant, and forms the most valuable part of Ptolemy's works. He then treats of the galaxy, or milky-way; also of the planetary aspects, with the rising and setting of the sun, moon, and stars.

In the 9th book, he treats of the order of the sun, moon, and planets, with the periodical revolutions of the five planets, Mercury, Venus, Mars, Jupiter, and Saturn; he then gives tables of the mean motions, beginning with the theory of Mercury, and showing its various phenomena with respect to the earth.

The 10th book begins with the theory of the planet Venus, as to its greatest distance from the sun; of its epicycle, excentricity, and periodical motions; and then treats of the same particulars in the planet Mars.

In the 11th book he considers the same circumstances in the theory of the planets Jupiter and Saturn. He also corrects all the planetary motions from observations made from the time of Nabonazar to his own.

The 12th book treats of the retrogressive motion of the several planets; giving also tables of their stations, and of the greatest distances of Venus and Mercury from the sun.

The 13th book relates to the several hypotheses of the latitude of the five planets; of the greatest latitude, or inclination of the orbits of the five planets, which are computed and disposed in tables; of the rising and setting of the planets, with tables of them. Then follows a conclusion or summing up of the whole work.

This great work of Ptolemy will always be valuable on account of the observations he gives of the places of the stars and planets in former times, and according to ancient philosophers and astronomers that were then extant; but principally on account of the large and curious catalogue of the stars, which being compared with their places at present, we thence deduce the true quantity of their slow progressive motion according to the order of the signs, or of the precession of the equinoxes.

Another great and important work of Ptolemy was, his Geography, in 7 books; in which, with his usual sagacity, he searches out and marks the situation of places according to their latitudes and longitudes; being the first that did so. Though this work must needs fall far short of perfection, for the want of necessary observations, yet it is of considerable merit, and has been very useful to modern geographers. Cellarius indeed suspects, and he was a very competent judge, that Ptolemy did not use all the care and application which the nature of his work required; and his reason is, that the author delivers himself with the same fluency and appearance of certainty, concerning things and places at the remotest distance, which it was impossible he could know any thing of, that he does concerning those which lay the nearest to him, and fall the most under his cognizance. Salmasius had before made some remarks to the same purpose on this work of Ptolemy. The Greek text of this work was first published by itself at Basil in 1533, in 4to: afterward with a Latin version and notes by Gerard Mercator at Amsterdam, 1605; which last edition was reprinted at the same place, 1618, in folio, with neat geographical tables, by Bertius.

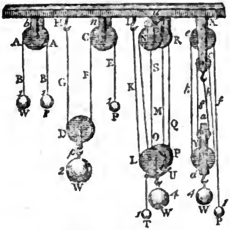
Other works of Ptolemy, though less considerable than these two, are still extant. As, Libri quatuor de Judiciis Astrorum, on the first two books of which Cardan wrote a commentary.—Fructus Librorum suorum; a kind of supplement to the former work.—Recensio Chronologica Regum: this, with another work of Ptolemy, De Hypothesibus Planetarum, was published in 1620, 4to, by John Bainbridge, the Savilian professor of astronomy at Oxford: and Scaliger, Petavius, Dodwell, and the other chronological writers, have made great use of it.—Apparentiæ Stellarum Inerrantium: this was published at Paris by Petavius, with a Latin version, 1630, in folio; but from a mutilated copy, the defects of which have since been supplied from a perfect one, which Sir Henry Saville had communicated to archbishop Usher, by Fabricius, in the 3d volume of his Bibliotheca Græca.—Elementorum Harmonicorum libri tres; published in Greek and Latin, with a commentary by Porphyry the philosopher, by Dr. Wallis at Oxford, 1682, in 4to; and afterwards reprinted there, and inserted in the 3d volume of Wallis's works, 1699, in folio.

Mabillon exhibits, in his German Travels, an effigy of Ptolemy looking at the stars through an optical tube; which effigy, he says, he found in a manuscript of the 13th century, made by Conradus a monk. Hence some have fancied, that the use of the telescope was known to Conradus. But this is only matter of mere conjecture, there being no facts or testimonies, nor even probabilities, to support such an opinion. It is rather likely that the tube was nothing more than a plain open one, employed to strengthen and defend the eye-sight, when looking at particular stars, by excluding adventitious rays from other stars and objects; a contrivance which no observer of the heavens can ever be supposed to have been without.

PULLEY, one of the five mechanical powers; consisting of a little wheel, being a circular piece of wood or metal, turning on an axis, and having a channel around its edge or circumference, in which a cord slides and so raises up weights.

The Latins call it trochlea; and the seamen, when fitted with a rope, a tackle. An assemblage of several pulleys is called a system of pulleys, or polyspaston: some of which are in a block or case, which is fixed; and others in a block which is moveable, and rises with the weight. The wheel or rundle is called the sheave or shiver; the axis on which it turns, the gudgeon; and the fixed piece of wood or iron, into which it is placed, is called the block.

Doctrine of the PULLEY.—1. If the equal weights P and W hang by the cord BB upon the pulley A, whose block *b* is fixed to the beam HI, they will counterpoise each other, just in the same manner as if the cord were cut in the middle, and its two ends hung upon the hooks fixed in the pulley at A and A, equally distant from the centre.



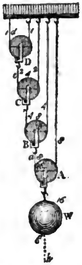
Hence, a single pulley, if the lines of direction of the power and the weight be tangents to the periphery, neither assists nor impedes the power, but only changes its direction. The use of the pulley therefore, is when the vertical direction of a power is to be changed into an horizontal one; or an ascending direction into a descending one; &c. This is found a good provision for the safety of the workmen employed in drawing with the pulley. And this change of direction by means of a pulley has this further advantage; that if any power can exert more force in one direction than another, we are hence enabled to employ it with its greatest effect; as for the convenience of a horse to draw in a horizontal direction, or such like.

But the great use of the pulley is in combining several of them together; thus forming what Vitruvius and others call polyspasta; the advantages of which are, that the machine takes up but little room, is easily removed, and raises a very great weight with a moderate power.

2. When a weight W hangs at the lower end of the moveable block *p* of the pulley D, and the cord GF goes under the pulley, it is evident that the part G of the cord bears one half of the weight W, and the part F the other half of it; for they bear the whole between them; therefore whatever holds the upper end of either rope, sustains one half of the weight; and thus the power P, which draws the cord F by means of the cord E, passing over the fixed pulley C, will sustain the weight W when its intensity is only equal to the half of W; that is, in the case of one moveable pulley, the power gained is as 2 to 1, or as the number of ropes G and F to the one rope E.

In like manner, in the case of two moveable pulleys P and L, each of these also doubles the power, and produces a gain of 4 to 1, or as the number of the ropes Q, M, S, K, sustaining the weight W, to the 1 rope O sustaining the power T; that is, W is to T as 4 to 1. And so on, for any number of moveable pulleys, viz, 3 such pulleys producing an increase of power as 6 to 1; 4 pulleys, as 8 to 1; &c; each pulley adding 2 to the number. Also the effect is the same, when the pulleys are disposed as in the fixed block X, and the other two as in the moveable block Y; these in the lower block giving the same advantage to the power, when they rise all together in one block with the weight.

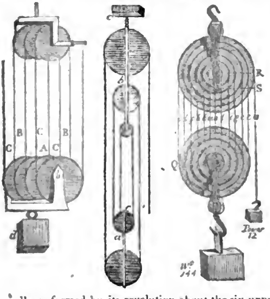
But if the lower pulleys do not rise all together in one block with the weight, but act upon one another, having the weight only fastened to the lowest of them, the force of the power is still more increased, each power doubling the former numbers, the gain of power in this case proceeding in the geometrical progression, 1, 2, 4, 8, 16, &c, according to the powers of 2; whereas in the former case, the gain was only in arithmetical progression, increasing by the addition of 2. Thus, a power whose intensity is equal to 8lb applied at *a* will, by means of the lower pulley A, sustain 16lb; and a power equal to 4lb at *b*, by means of the pulley, will sustain the power of 8lb acting at *a*, and consequently the weight of 16lb at W; also a third power equal to 2lb at *c*, by means of the pulley C, will sustain the power of 4lb at *b*; and a fourth power of 1lb at *d*, by means of the pulley D, will sustain the power 2 at *c*, and consequently the power 4 at B, and the power 8 at A, and the weight 16 at W.



3. It is to be noted however, that, in whatever proportion the power is gained, in that very same proportion is the length of time increased to produce the same effect. For when a power moves a weight by means of several pulleys, the space passed over by the power is to the space passed over by the weight, as the weight is to the power. Hence, the smaller a force is, that sustains a weight by means of pulleys, the slower is the weight raised; so that what is saved or gained in force, is always spent or lost in time: which is the general property of all the mechanical powers.

The usual methods of arranging pulleys in their blocks, may be reduced to two. The first consists in placing them one by the side of another, on the same pin; the other, in placing them directly under each other, on separate pins. Each of these methods however is liable to inconvenience; and Mr. Smeaton, to avoid the impediments to which these combinations are subject, proposes to combine these two methods in one. See the Philos. Trans. vol. 47, pa. 494. Some instances of such combinations of pulleys are exhibited in the following figures; besides which, there are also other varieties of forms.

A very considerable improvement in the construction of pulleys has been made by Mr. James White, who has obtained a patent for his invention, and of which he gives the following description. The last of the three following figures shows the machine, consisting of two pulleys Q and R, one fixed and the other moveable. Each of these has six concentric grooves, capable of having a line put round them, and thus acting like as many different pulleys, having diameters equal to those of the grooves. Supposing then each of the grooves to be a distinct pulley, and that all their diameters were equal, it is evident that if the weight 144 were to be raised by pulling at s till the pulleys touch each other, the first pulley must receive the length of line as many times as there are parts of the line hanging between it and the lower pulley. In the present case, there are 12 lines, *b*, *d*, *f*, &c, hanging between the



two pulleys, formed by its revolution about the six upper and lower grooves. Hence as much line must pass over the uppermost pulley as is equal to 12 times the distance of the two. But, from an inspection of the figure, it is evident, that the second pulley cannot receive the full quantity of line by as much as is equal to the distance between it and the first. In like manner, the third pulley receives less than the first by as much as is the distance between the first and third; and so on to the last, which receives only $\frac{1}{12}$th of the whole. For this receives its share of line *n* from a fixed point in the upper frame, which gives it nothing; while all the others in the same frame receive the line partly by turning to meet it, and partly by the line coming to meet them.

Supposing now these pulleys to be equal in size, and to move freely as the line determines them; it appears evident, from the nature of the system, that the number of their revolutions, and consequently their velocities, must be in proportion to the number of suspending parts that are between the fixed point above mentioned, and each pulley, respectively. Thus the outermost pulley would go 12 times round in the time that the pulley under which the part *n* of the line, if equal to it, would revolve only once; and the intermediate times and velocities would be a series of arithmetical proportionals, of which, if the first number were 1, the last would always be equal to the whole number of terms. Since then the revolutions of equal and distinct pulleys are measured by their velocities, and that it is possible to find any proportion of velocity, on a single body running on a centre, viz, by finding proportionate distances from that centre; it follows, that if the diameters of certain grooves in the same substance be exactly adapted to the above series (the line itself being supposed inelastic, and of no magnitude) the necessity of using several pulleys in each frame will be obviated, and with that some of the inconveniencies to which the use of the pulley is liable.

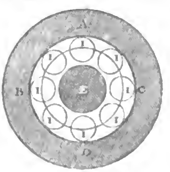
In the figure referred to, the coils of rope by which the weight is supported, are represented by the lines *a*, *b*, *c* &c; *a* is the line of traction, commonly called the fall, which passes over and under the proper grooves, until it is fastened to the upper frame just above *n*. In practice, however, the grooves are not arithmetical proportions, nor can they be so; for the diameter of the rope employed must in all cases be deducted from each term; without which the smaller grooves, to which the said diameter bears a larger proportion than to the larger ones, will tend to rise and fall faster than they, and thus introduce worse defects than those which they were intended to obviate.

The principal advantage of this kind of pulley is, that it destroys lateral friction, and that kind of shaking motion which is so inconvenient in the common pulley. And lest (says Mr. White) this circumstance should give the idea of weakness, I would observe, that to have pins for the pulleys to run on, is not the only nor perhaps the best method; but that I sometimes use centres fixed to the pulleys, and revolving on a very short bearing in the side of the frame, by which strength is increased, and friction very much diminished; for to the last moment the motion of the pulley is perfectly circular: and this very circumstance is the cause of its not wearing out in the centre as soon as it would, assisted by the ever increasing irregularities of a gullied bearing. These pulleys, when well executed, apply to jacks and other machines of that nature with peculiar advantage, both as to the time of going and their own durability; and it is possible to produce a system of pulleys of this kind of six or eight parts only, and adapted to the pockets, which, by means of a skain of sewing silk, or a clue of common thread, will raise upwards of an hundred weight.

As a system of pulleys has no great weight, and lies in a small compass, it is easily carried about, and can be applied for raising weights in a great many cases, where other engines cannot be used. But they are subject to a great deal of friction, on the following accounts; viz, 1st, because the diameters of their axes bear a very considerable proportion to their own diameters; 2d, because in working they are apt to rub against each other, or against the sides of the block; 3dly, because of the stiffness of the rope that goes over and under them. See Ferguson's Mech. pa. 37, 4to.

But the friction of the pulley is now reduced to nothing as it were, by the ingenious Mr. Garnett's patent friction rollers, which produce a great saving of labour and expense, as well as in the wear of the machine, both when applied to pulleys and to the axles of wheel-carriages. His general principle is this: between the axle and nave, or centre pin and box, a hollow space is left, to be filled up by solid equal rollers nearly touching each other. These are furnished with axles inserted into a circular ring at each end, by which their relative distances are preserved; and they are kept parallel by means of wires fastened to the rings between the rollers, and which are rivetted to them.

The above contrivance is exhibited in the annexed figure; where ABCD represents a piece of metal to be inserted into the box or nave, of which E is the centre-pin or axle, and 1, 1, 1, &c, rollers of metal having axes inserted in the brazen circle which passes through their centres; and both circles being rivetted together by means of bolts passing between the rollers from one side of the nave to the other; and thus they are always kept separate and parallel.



PUMP, in Hydraulics, a machine for raising water, and other fluids.—Pumps are probably of very ancient use. Vitruvius ascribes the invention to Ctesebes of Athens, some say of Alexandria, about 120 years before Christ. They are now of various kinds. As the Sucking Pump, the Lifting Pump, the Forcing Pump, Ship Pumps, Chain Pumps, &c. By means of the lifting and forcing pumps, water may be raised to any height, with a sufficient power, and an adequate apparatus: but by the sucking pump, the water being only raised by the general pressure of the atmosphere on the surface of the well, is limited in its ascent to about 33 or 34 feet; though in practice it is seldom applied to the raising it much above 28; because, from the variations observed in the barometer, it appears that the air may sometimes be lighter than 33 feet of water; and whenever that happens, for want of the due counterpoise, this pump will fail in its performance.

The Common Sucking PUMP.—This consists of a pipe, of wood or metal, open at both ends, having a fixed valve in the lower part of it opening upwards, and a moveable valve or bucket by which the water is drawn or lifted up. This bucket is just the size of the bore of the pump-pipe, in that part where it works, and leathered round so as to fit it very close, that no air may pass by the sides of it; the valve hole being in the middle of the bucket. The bucket is commonly worked in the upper part of the barrel by a short rod, and another fixed valve placed just below the descent of the bucket. Thus, (fig. 1, pl. 28), AB is the pump-pipe, C the lower fixed valve, opening upwards, and D is the bucket, or moving valve, also opening upwards.

In working the pump; draw up the bucket D, by means of the pump rod, having any kind of a handle fixed to it: this draws up the water that is above it, or if not, the air; in either case the water pushes up the valve C, and enters to supply the void left between C and D, being forced up by the pressure of the atmosphere on the surface of the water in the well below. Next, the bucket D is pushed down, which shuts the valve C, and prevents the return of the water downwards, which opens the valve D, by which the water ascends above it. And thus, by repeating the strokes of the pump-rod handle, the valves alternately open and shut, and the water is drawn up at every stroke, and runs out at the nozle or spout near the top.

The Lifting PUMP differs from the sucking pump only in the disposition of its valves and the form of its piston frame. This kind of pump is represented in fig. 2, pl. 28; where the lower valve D is moveable, being worked up and down with the pump rod, which lifts the water up, and so opens the upper valve C, which is fixed, and permits the water to issue through it, and run out at top. Then as the piston D descends, the weight of the water above C shuts that valve C, and so prevents its return, till that valve be opened again by another lift of the piston D. And so on alternately.

The Forcing PUMP raises the water through the sucker, or lower valve C (fig. 3, pl. 28), in the same manner as the sucking pump; but as the piston or plunger D has no valve in it, the water cannot get above it when this is pushed down again; instead of which, a side pipe is inserted between C and D, having a fixed valve at E opening upwards, through which the water is forced out of the pump by pushing down the plunger D.

To the forcing pump is sometimes adapted an air vessel, in which the air being compressed by the water, by its elasticity acts upon the water again, and forces it out to a great distance, and in a continued stream, instead of by jets or jerks. So, Newsham's engine, for extinguishing fires, consists of two forcing pumps, which alternately drive water into a close vessel of air, by which means the air in it is condensed, and compresses the water so strongly, that it rushes out with great impetuosity and force through a pipe that comes down into it, making a continued uniform stream.—By means of forcing pumps, water may be raised to any height whatever above the level of a river or spring; and machines may be contrived to work these pumps, either by a running stream, a fall of water, or by horses.

Observations on Pumps.—The force required to work a pump, is equal to the weight of water raised at each stroke, or equal to the weight of water filling the cavity of the pipe, and its height equal to the length of the stroke made by the piston. Hence if d denote the diameter of the pipe, and l the length of the stroke, both in inches; then is $\cdot 7854d^2l$ the content of the water raised at a stroke, in inches, or $\cdot 0028d^2l$ in ale gallons; and the weight of it is $\frac{d^2l}{220}$ ounces or $\frac{d^2l}{3520}$ lb. But if the handle of the pump be a lever which gains in the power of p to 1, the force of the hand to work the pump will be only $\frac{d^2l}{3520p}$ lb, or, when p is 5 for instance, it will be $\frac{d^2l}{17600}$ lb. And all these over and above the friction of the moving parts of the pump.

Ctesebes's PUMP, acts both by suction and by pression. Thus, a brass cylinder ABCD (fig. 5, pl. 28), furnished with a valve at L, is placed in the water. In this is fitted the piston KM, made of green wood, which will not swell in the water, which is adjusted to the aperture of the cylinder with a covering of leather, but without any valve. Another tube NH is fitted on at H, with a valve I opening upwards.—Now the piston being raised, the water opens the valve L, and rises into the cavity of the cylinder.—When the piston is depressed again, the valve I is opened, and the water is driven up through the tube HN. This was the pump used among the ancients, and that from which the others have been deduced. Sir Samuel Morland has endeavoured to increase its force by lessening the friction; which he has done in a great degree. There are various kinds of pumps used in ships, for throwing the water out of the hold, and on other occasions, as the chain pump, &c.

A TABLE by which the Quantity and Weight of Water in a Cylindrical Bore of any given Diameter and Perpendicular Height, may be found; and consequently, the Degree of Power that will be requisite to work any Hydraulic Engine. By JAMES FERGUSON, F. R. S.

Feet High.	Diameter of the Cylindrical Bore one Inch.		
	Quantity of Water in Cubic Inches.	Weight of Water in Troy Ounces.	In Avoirdupois Ounces.
1	9·4247781	4·9712340	5·4541539
2	18·8495562	9·9424680	10·9083078
3	28·2743343	14·9137020	16·3624617
4	37·6991124	19·8849360	21·8166156
5	47·1238905	24·8561700	27·2707695
6	56·5486686	29·8274040	32·7249234
7	65·9734467	34·7986380	38·1790773
8	75·3982248	39·7698720	43·6332312
9	84·8230029	44·7411060	49·0873851

The numbers to the right hand from the points in each column are decimals.

For tens of feet high, remove the decimal points one place forward; for hundreds of feet, two places; for thousands of feet, three places; and so on.

Then, multiply the sums by the square of the diameter of the given bore; and the products will be the quantity of water in the pipe, in cubic inches, and in troy and avoirdupois ounces.

EXAMPLE.—Qu. *The Quantity and Weight of Water in an upright Pipe whose Bore is* 10 *Inches in Diameter, and its Height* 208 *Feet?*—The Square of 10 is 100.

Feet high.		Cubic Inches.		Troy Ounces.		Avoird. Ounces.
200	-	1884·95562	-	994·24680	-	1090·83078
8	-	75·39822	-	39·76897	-	43·63323
208	-	1960·35384	-	1034·01577	-	1134·46401
Multiply by	-	100	-	100	-	100
Ans.		196035·384	-	103401·577	-	113446·401

Which number of cubic inches being divided by 231 (the number of cubic inches in a wine gallon) gives $848\frac{6}{10}$ for the number of gallons of water in the pipe; and the respective weights, 103401·577 and 113446·401, being divided by 12 and by 16, give $8616\frac{8}{10}$ for the number of troy pounds, and $7090\frac{4}{10}$ for the number of avoirdupois pounds of water. The power of an engine equal to the weight will just balance the water; but the engine must have as much more power as will be sufficient to overcome the friction of its working parts.—In pumps, it matters not what the diameter of any part of the bore be, besides that part in which the piston or bucket works; for, the power requisite to work them will be the same as if the whole bore was of that diameter throughout.

Air-PUMP, in Pneumatics, is a machine, by means of which the air is emptied out of vessels, and a kind of vacuum produced in them. For the particulars of which, see AIR-*Pump*.

PUNCHEON, a measure for liquids, containing $\frac{1}{3}$ of a tun, or a hogshead and $\frac{1}{3}$, or 84 gallons.

PUNCHINS, or PUNCHIONS, in Building, short pieces of timber placed to support some considerable weight.

PUNCTATED *Hyperbola*, in the higher geometry, an hyperbola, whose conjugate oval is infinitely small, that is, a point.

PUNCTUM *ex Comparatione*, is either focus, in the ellipse or hyperbola; so called by Apollonius, because the rectangle under two abscisses made at the focus, is equal to one-fourth part of what he calls the figure, which is the square of the conjugate axis, or the rectangle under the transverse and the parameter.

PUNCTUM *Duplex*, double point, in the higher geometry, a point where two branches of a curve intersect. See CURVE, LEMNISCATE, &c.

PURBACH (GEORGE), a very eminent mathematician and astronomer, was born at Purbach, a town upon the confines of Bavaria and Austria, in 1423, and educated at Vienna. He afterwards visited the most celebrated universities in Germany, France, and Italy; and found a particular friend and patron in Cardinal Cusa at Rome. Returning to Vienna, he was appointed mathematical professor, in which office he continued till his death, which happened in 1461, in the 39th year of his age only, to the great loss of the learned world.

Purbach composed a great number of pieces, on mathematical and astronomical subjects; and his fame brought many students to Vienna, and among them, the celebrated Regiomontanus, between whom and Purbach there subsisted the strictest friendship and union of studies till the death of the latter. These two celebrated mathematicians laboured together to improve every branch of learning, by all the means in their power, though astronomy seems to have been the favourite of both; and had not the immature death of Purbach prevented his further pursuits, there is no doubt but that, by their joint industry, astronomy would have been cultivated to a very great degree. That this is not merely surmise, may be learnt from those improvements which Purbach actually did make, to render the study of it more easy and practicable. His first essay was, to amend the Latin translation of Ptolemy's Almagest, which had been made from the Arabic version; which he did, not by the help of the Greek text, for he was unacquainted with that language, but by drawing the most probable conjectures from a strict attention to the sense of the author.

He then proceeded to other works, and among them, he wrote a tract, which he entitled, An Introduction to Arithmetic; then a treatise on Gnomonics, or Dialling, with tables suited to the difference of climates or latitudes; also a small tract concerning the Altitudes of the Sun, with a table; also, Astrolabic Canons, with a table of the parallels, proportioned to every degree of the equinoctial.

After this, he constructed Solid Spheres, or Celestial Globes, and composed a new table of fixed stars, adding the longitude by which every star, since the time of Ptolemy, had increased. He also invented various other instruments, among which was the Gnomon, or Geometrical Square, with canons and a table for the use of it.

He not only collected the various tables of the Primum Mobile, but added new ones. He made very great improvements in Trigonometry, and by introducing the table of Sines, by a decimal division of the radius, he quite changed the appearance of that science: he supposed the radius to be divided into 600,000 equal parts, and computed the sines of the arcs, for every ten minutes, in such equal parts of the radius, by the decimal notation, instead of the duodecimal one delivered by the Greeks, and preserved even by the Arabians till our author's time; a project which was completed by his friend Regiomontanus, who computed the sines to every minute of the quadrant, in 1,000,000th parts of the radius.

Having prepared the tables of the fixed stars, he next undertook to reform those of the planets, and constructed some entirely new ones. Having finished his tables, he wrote a kind of Perpetual Almanac, but chiefly for the moon, answering to the periods of Meton and Calippus; also an Almanac for the Planets, or, as Regiomontanus afterwards called it, an Ephemeris, for many years. But observing that there were some planets in the heavens at a great distance from the places where they were described to be in the tables, particularly the sun and moon (the eclipses of which were observed frequently to happen very different from the times predicted), he applied himself to construct new tables, particularly adapted to eclipses; which were long after famous for their exactness. To the same time may be referred his finishing that celebrated work, entitled, A New Theory of the Planets, which Regiomontanus afterwards published the first of all the works executed at his new printing house.

PURE *Hyperbola*, is an Hyperbola without any oval, node, cusp, or conjugate point; which happens through the impossibility of two of its roots.

PURE *Mathematics, Proposition, Quadratics*, &c. See the several articles.

PURLINES, in Architecture, those pieces of timber that lie across the rafters on the inside, to keep them from sinking in the middle of their length.

PYRAMID, a solid having any plane figure for its base, and its sides triangles whose vertices all meet in a point at the top, called the vertex of the pyramid; the base of each triangle being the sides of the plane base of the pyramid.—The number of triangles is equal to the number of the sides of the base; and a cone is a round pyramid, or one having an infinite number of sides.—The pyramid is also denominated according to the figure of its base, being triangular when the base is a triangle, quadrangular when a quadrangle, &c.

The *axis* of the pyramid, is the line drawn from the vertex to the centre of the base; and when this axis is perpendicular to the base, the pyramid is said to be a right one; otherwise it is oblique.

1. A pyramid may be conceived to be generated by a line moved about the vertex, and so carried round the perimeter of the base.

2. All pyramids having equal bases and altitudes, are equal to one another: whatever may be the figures of their bases.

3. Every pyramid is equal to one-third of the circumscribed prism, or a prism of the same base and altitude; and therefore the solid content of the pyramid is found by multiplying the base by the perpendicular altitude, and taking $\frac{1}{3}$ of the product.

4. The upright surface of a pyramid, is found by adding together the areas of all the triangles which form that surface.

5. If a pyramid be cut by a plane parallel to the base, the section will be a plane figure similar to the base; and these two figures will be in proportion to each other as the squares of their distances from the vertex of the pyramid.

6. The centre of gravity of a pyramid is distant from the vertex $\frac{3}{4}$ of the axis.

Frustum of a PYRAMID, is the part left at the bottom when the top is cut off by a plane parallel to the base.

The solid content of the frustum of a pyramid is found, by first adding into one sum the areas of the two ends and the mean proportional between them, the 3d part of which sum is a medium section, or it is the base of an equal prism of the same altitude; and therefore this medium area or section multiplied by the altitude gives the solid content. So, if A denote the area of one end, a the area of the other end, and h the height; then $\frac{1}{3}(A + a + \sqrt{Aa})$ is the medium area or section: and $\frac{1}{3}(A + a + \sqrt{Aa}) \times h$ is the solid content.

PYRAMIDS *of Egypt*, are very numerous; but the most remarkable are the three pyramids of Memphis, or, as they are now called, of Gheisa or Gize. These are square pyramids, and the greatest of them measures 700 feet on each side of the base, and the oblique height or slant side measures the same; and its base covers, or stands upon, nearly 11 acres of ground. It is thought by some that these pyramids were designed and used as gnomons, for astronomical purposes; and it is remarkable that their four sides are accurately in the direction of the four cardinal points of the compass, east, west, north, and south.

PYRAMIDAL *Numbers*, are the sums of polygonal numbers, collected after the same manner as the polygonal numbers themselves are found from arithmetical progressions. These are particularly called First pyramidals. The sums of first pyramidals are called second pyramidals; and the sums of the 2d are 3d pyramidals; and so on. Particularly, those arising from triangular numbers, are called Prime Triangular Pyramidals; those arising from pentagonal numbers, are called Prime Pentagonal Pyramidals; and so on.

The numbers	1,	4,	10,	20,	35, &c,
formed by adding the triangulars	1,	3,	6,	10,	15, &c,

are usually called simply by the name of pyramidals; and the general formula for finding them is $n \times \frac{n-1}{2} \times \frac{n-2}{3}$; so the 4th pyramidal is found by substituting 4 for n; the 5th by substituting 5 for n; &c. See FIGURATE *Numbers*, and POLYGONAL *Numbers*.

PYRAMIDOID, is sometimes used for the parabolic spindle, or the solid formed by the rotation of a semiparabola about its base or greatest ordinate. See PARABOLIC *Spindle*.

PYROMETER, or fire-measurer, a machine for measuring the expansion of solid bodies by heat. Musschenbroek was the first inventor of this instrument; though it has since received several improvements by other philosophers. He has given a table of the expansions of the different metals, with various degrees of heat. Having prepared cylindric rods of iron, steel, copper, brass, tin, and lead, he exposed them first to a pyrometer with one flame in the middle; then with two flames; then successively with three, four, and five flames. The effects were as in the following Table, where the degrees of expansion are marked in parts equal to the 12500th part of an inch.

Expansion of	Iron	Steel	Copp.	Brass	Tin	Lead
By 1 flame	80	85	89	110	153	155
By 2 flames placed close together	117	123	115	220		274
By 2 flames at 2½ inches distant	109	94	92	141	219	263
By 3 flames close together	142	168	193	275		
By 4 flames close together	211	270	270	361		
By 5 flames	230	310	310	377		

Tin easily melts when heated by two flames placed close together; and lead with three flames close together, when they burn long.

It hence appears that the expansion of any metal is in a less degree than the number of flames: so two flames give less than a double expansion, three flames less than a triple expansion, and so on, always more and more below the ratio of the number of flames. And the flames placed together cause a greater expansion, than with an interval between them.

For the construction of Musschenbroek's pyrometer, with alterations and improvements upon it by Desaguliers, see Desag. Exper. Philos. vol. 1, pa. 421; see also Musschenbroek's translation of the Experiments of the Academy del Cimento, printed at Leyden in 1731; and for a pyrometer of a new construction, by which the expansions of metals in boiling fluids may be examined and compared with Fahrenheit's thermometer, see Mussch. Introd. Philos. Nat. 4to, 1762, vol. 2, pa. 610.

But as it has been observed, that Musschenbroek's pyrometer was liable to some objections, these have been removed in a great measure by Ellicott, who has given a description of his improved pyrometer in the Philos. Trans. numb. 443. This instrument measures the expansions to the 7200th part of an inch; and by means of it, Mr. Ellicott found, on a medium, that the expansions of bars of different metals, as nearly of the same dimensions as possible, by the same degree of heat, were as below:

Gold	Silver	Brass	Copper	Iron	Steel	Lead
73	103	95	89	60	56	149

The great difference between the expansions of iron and brass, has been applied with good success to remove the irregularities in pendulums arising from heat. Philos. Trans. vol. 47, pa. 485.

Mr. Graham used to measure the minute expansions of metal bars, by advancing the point of a micrometer screw, till it sensibly stopped against the end of the bar to be measured. This screw, being small and very lightly hung, was capable of agreement within the 3000 or 4000th part of an inch. And on this general principle Mr. Smeaton contrived his pyrometer, in which the measures are determined by the contact of a piece of metal with the point of a micrometer-screw. This instrument makes the expansions sensible to the 2345th part of an inch. And when it is used, both the instrument and the bar to be measured are immerged in a cistern of water, heated to any degree, up to boiling, by means of lamps placed under the cistern; and the water communicates the same degree of heat to the instrument and bar, and to a mercurial thermometer immerged in it, for ascertaining that degree.

With this pyrometer Mr. Smeaton made several experiments, which are arranged in a table; and he remarks, that their result agrees very well with the proportions of expansions of several metals given by Mr. Ellicott. The following table shows how much a foot in length of each metal expands by an increase of heat corresponding to 180° of Fahrenheit's thermometer, or to the difference between the temperatures of freezing and boiling water, expressed in the 10000th part of an inch.

1.	White glass barometer tube	100
2.	Martial regulus of antimony	130
3.	Blistered steel	138
4.	Hard steel	147
5.	Iron	151
6.	Bismuth	167
7.	Copper, hammered	204
8.	Copper 8 parts, mixed with 1 part tin	218
9.	Cast brass	225
10.	Brass 16 parts, with 1 of tin	229
11.	Brass wire	232
12.	Speculum metal	232
13.	Spelter solder, viz 2 parts brass and 1 zinc	247
14.	Fine pewter	274
15.	Grain tin	298
16.	Soft solder, viz lead 2 and tin 1	301
17.	Zinc 8 parts, with tin 1, a little hammered	323
18.	Lead	344
19.	Zinc or spelter	353
20.	Zinc hammered half an inch per foot	373

For a further account of this instrument, with its use, see Philos. Trans. vol. 48, pa. 598.

Mr. Ferguson has constructed, and described a pyrometer (Lect. on Mechanics, Suppl. pa. 7, 4to), which makes the expansion of metals by heat visible to the 45000th part of an inch. And another plan of a pyrometer has lately been invented by M. Deluc, in consequence of a hint suggested to him by Mr. Ramsden: for an account of which, with the principle of its construction and use, both in the comparative measure of the expansions of bodies by heat, and the measure of their absolute expansion, as well as the experiments made with it, see M. Deluc's elaborate essay on pyrometry &c, in the Philos. Trans. vol. 68, pa. 419 &c.

Other accurate and ingenious contrivances, for the measuring of expansions by heat, have been made by Mr. Ramsden; which he has successfully applied in the case of the measuring rods and chains lately employed, by General Roy and Col. Williams, in measuring the base on Hounslow Heath, &c; which determine the expansions, to great minuteness, for each degree of the thermometer. See Philos. Trans. 1785, &c.

PYROPHORUS, the name usually given to that substance by some called black phosphorus; being a chemical preparation possessing the singular property of kindling spontaneously when exposed to the air; which was accidentally discovered by M. Homberg, who prepared it of alum and human fæces. Though it has since been found, by the son of M. Lemeri, that the fæces are not necessary to it, but that honey, sugar, flour, and any animal or vegetable matter, may be used instead of the fæces; and M. De Suvigny has shown that most vitriolic salts may be substituted for the alum. See Priestley's Obser. on Air, vol. 3, Append. pa. 386, and vol. 4, Append. pa. 479.

PYROTECHNY, the art of fire, or the science which teaches the application and management of fire in several operations. Pyrotechny is of two kinds, military and chemical.

Military PYROTECHNY, is the science of artificial fire-works, and fire-arms, teaching the structure and use both of those employed in war, as gunpowder, cannon, shells, carcasses, mines, fusees, &c; and of those made for amusement, as rockets, stars, serpents, &c.—Some call pyrotechny by the name artillery; though that word is usually confined to the instruments employed in war. Others choose to call it pyrobology, or rather pyroballogy, or the art of missile fires.—Wolfius has reduced pyrotechny into a kind of mixed mathematical art. Indeed it will not allow of geometrical demonstrations; but he brings it to tolerable rules and reasons; whereas it had formerly been treated by authors at random, and without regard to any reasons at all. See the several articles CANNON, GUNPOWDER, ROCKET, SHELL, &c.

Chemical PYROTECHNY, is the art of managing and applying fire in distillations, calcinations, and other operations of chemistry. Some reckon a third kind of pyrotechny, viz, the art of fusing, refining, and preparing metals.

PYTHAGORAS, one of the most celebrated philosophers of antiquity, was born about the 47th Olympiad, or 590 years before Christ. His father's principal residence was at Samos, but being a travelling merchant, his son Pythagoras was born at Sidon in Syria; but soon returning home again, our philosopher was brought up at Samos, where he was educated in a manner that was answerable to the great hopes that were conceived of him. He was called "the youth with a fine head of hair;" and from the great qualities that soon appeared in him, he was regarded as a good genius sent into the world for the benefit of mankind.

Samos however afforded no philosophers capable of satisfying his thirst for knowledge; and therefore, at 18 years of age, he resolved to travel in quest of them elsewhere. The fame of Pherecydes drew him first to the island of Syros: from hence he went to Miletus, where he conversed with Thales. He then travelled to Phœnicia, and stayed some time at Sidon, the place of his birth; and from hence he passed into Egypt, where Thales and Solon had been before him.

Having spent 25 years in Egypt, to acquire all the learning and knowledge he could procure in that country, he travelled with the same view through Chaldea, and visited Babylon and India. Returning after some time, he went to Crete; and from hence to Sparta, to be instructed in the laws of Minos and Lycurgus. He then returned again to Samos; but finding it under the tyranny of Polycrates, he quitted it again, and visited the several countries of Greece: passing through Peloponnesus, he stopped at Phlius, where Leo then reigned, who was much surprised with his eloquence and wisdom.

From Peloponnesus he went into Italy, and passed some time at Heraclea, and at Tarentum, but made his chief residence at Croton; where, after reforming the manners of the citizens by preaching, and establishing the city by wise and prudent counsels, he opened a school to display the treasures of wisdom and learning he possessed. It is not to be wondered, that he was soon attended by a crowd of disciples, who repaired to him from different parts of Greece and Italy.

He gave his scholars the rules of the Egyptian priests, and made them pass through the austerities which he himself had endured. He at first enjoined them a five years silence in the school, during which they were only to hear; after which, leave was given them to start questions, and to propose doubts, under the caution however, to say, "not a little in many words, but much in a few." Having gone through their probation, they were obliged, before they were admitted, to bring all their fortune into the common stock, which was managed by persons chosen on purpose, and called œconomists, and the whole community had all things in common.

The desire of concealing their mysteries induced the Egyptians to make use of three kinds of styles, or ways of expressing their thoughts; the simple, the hieroglyphical, and the symbolical. In the simple, they spoke plainly and intelligibly, as in common conversation; in the hieroglyphical, they concealed their thoughts under certain images and characters; and in the symbolical, they explained them by short expressions, which, under a sense plain and simple, included another wholly figurative. Pythagoras borrowed these three different ways from the Egyptians, in all the instructions he gave; but chiefly imitated the symbolical style, which he thought very proper to inculcate the greatest and most important truths: for a symbol, by its double sense, the proper and the figurative, teaches two things at once; and nothing pleases the mind more, than the double image it represents to our view.

In this manner Pythagoras delivered many excellent things concerning God and the human soul, and a great variety of precepts, relating to the conduct of life, both political and civil; he made also some considerable discoveries and advances in the arts and sciences. Thus, among the works ascribed to him, there are not only books of physic, and books of morality, like that contained in what are called his Golden Verses, but treatises on politics and theology. All these works are lost: but the vastness of his mind appears from the wonderful things he performed. He delivered, as antiquity relates, several cities of Italy and Sicily from the yoke of slavery; he appeased seditions in others; and he softened the manners, and brought to temper the most savage and unruly spirits, of several people and tyrants. Phalaris, the tyrant of Sicily, it is said, was the only one who could withstand the remonstrances of Pythagoras; and he it seems was so enraged at his discourses, that he ordered him to be put to death. But though the lectures of the philosopher could make no impression on the tyrant, yet they were sufficient to reanimate the Sicilians, and to put them upon a bold action. In short, Phalaris was killed the same day that he had fixed for the death of the philosopher.

Pythagoras had a great veneration for marriage; and therefore himself married at Croton a daughter of one of the chief men of that city, by whom he had two sons and a daughter: one of the sons succeeded his father in the school, and became the master of Empedocles: the daughter, named Damo, was distinguished both by her learning and her virtues, and wrote an excellent commentary upon Homer. It is also related, that Pythagoras had given her some of his writings, with express commands not to impart them to any but those of his own family; to which Damo was so scrupulously obedient, that even when she was reduced to extreme poverty, she refused a great sum of money for them.

From the country in which Pythagoras thus settled and gave his instructions, his society of disciples was called the Italic sect of philosophers, and their reputation continued for some ages afterwards, when the Academy and the Lycæum united to obscure and swallow up the Italic sect. Pythagoras's disciples regarded the words of their master as the oracles of a god; his authority alone, though unsupported by reason, passed with them for reason itself: they looked on him as the most perfect image of God among men. His house was called the temple of Ceres, and his court-yard the temple of the Muses: and when he went into towns, it was said he went thither, "not to teach men, but to heal them."

Pythagoras however was persecuted by bad men in the latter years of his life; and some say he was killed in a tumult raised by them against him; but according to others, he died a natural death, at 90 years of age, about 497 years before Christ.

Besides the high respect and veneration the world has always had for Pythagoras, on account of the excellence of his wisdom, his morality, his theology, and politics, he was renowned as learned in all the sciences, and a considerable inventor of many things in them; as arithmetic, geometry, astronomy, music, &c. In arithmetic, the common multiplication table is, to this day, still called Pythagoras's table. In geometry, it is said he invented many theorems, particularly these three; 1st, Only three polygons, or regular plane figures, can fill up the space about a point, viz, the equilateral triangle, the square, and the hexagon: 2d, The sum of the three angles of every triangle, is equal to two right angles: 3d, In any right-angled triangle, the square on the longest side is equal to both the squares on the two shorter sides: for the discovery of this last theorem, some authors say he offered to the gods a hecatomb, or a sacrifice of a hundred oxen; Plutarch however says it was only one ox, and even that is questioned by Cicero, as inconsistent with his doctrine, which forbade bloody sacrifices: the more accurate therefore say, he sacrificed an ox made of flour, or of clay; and Plutarch even doubts whether such sacrifice, whatever it was, was made for the said theorem, or for the area of the parabola, which it was said Pythagoras also found out.

In astronomy his inventions were many and great. It is said he discovered, or maintained the true system of the world, which places the sun in the centre, and makes all the planes revolve about him; and from him it is to this day called the old or Pythagorean system; and is the same as that revived by Copernicus. He first discovered, that Lucifer and Hesperus were but one and the same, being the planet Venus, though formerly thought to be two different stars. The invention of the obliquity of the zodiac is likewise ascribed to him. He first gave to the world the name Κοσμος, *Kosmos*, from the order and beauty of all things comprehended in it; asserting that it was made according to musical proportion: for, as he held that the sun, by him and his followers termed the fiery globe of unity, was seated in the midst of the universe, and the earth and planets moving around him, so he held that the seven planets had an harmonious motion, and their distances from the sun corresponded to the musical intervals or divisions of the monochord.

Pythagoras and his followers held the transmigration of souls, making them successively occupy one body after another: on which account they abstained from flesh, and lived chiefly on vegetables. This he probably learnt in India.

PYTHAGORAS's *Table*, the same as the multiplication-table; which see.

PYTHAGOREAN, or PYTHAGORIC, *System*, among the ancients, was the same as the Copernican system among the moderns. In this system, the sun is supposed at rest in the centre, with the earth and all the planets revolving about him, each in their respective orbits. See SYSTEM.

It was so called, as having been maintained and cultivated by Pythagoras, and his followers; not that it was invented by him, for it was much older.

PYTHAGOREAN *Theorem*, is that in the 47th proposition of the first book of Euclid's Elements; viz, that in a right-angled triangle, the square of the longest side is equal to the sum of both the squares of the two shorter sides. It has been said that Pythagoras offered a hecatomb, or sacrifice of 100 oxen, to the gods, for inspiring him with the discovery of so remarkable a property.

PYTHAGOREANS, a sect of ancient philosophers, who followed the doctrines of Pythagoras. They were called the Italic sect, from the circumstance of his having settled in Italy. Out of his school proceeded the greatest philosophers and legislators, Zaleucus, Charondas, Archytas, &c. See the article PYTHAGORAS.

PYXIS *Nautica*, the seaman's compass.

Q.

QUADRAGESIMA, a denomination given to the time of lent, from its consisting of about 40 days; commencing on ash-wednesday.

QUADRAGESIMA *Sunday*, is the first sunday in lent, or the first sunday after ash-wednesday.

QUADRANGLE, or QUADRANGULAR *figure*, in Geometry, is a plane figure having four angles; and consequently four sides also.—To the class of quadrangles belong the square, parallelogram, trapezium, rhombus, and rhomboides.—A square is a regular quadrangle; a trapezium an irregular one.

QUADRANT, in Geometry, is either the quarter or 4th part of a circle, or the 4th part of its circumference; the arch of which therefore contains 90 degrees.

QUADRANT also denotes a mathematical instrument of great use in astronomy and navigation, for taking the altitudes of the sun and stars, as also taking angles in surveying, heights-and-distances, &c.—This instrument is variously contrived, and furnished with different apparatus, according to the various uses it is intended for; but they have all this in common, that they consist of the quarter of a circle, whose limb or arch is divided into 90° &c. Some have a plummet suspended from the centre, and are furnished either with plain sights, or a telescope, to look through.

The principal and most useful quadrants, are the common Surveying quadrant, the Astronomical quadrant, Adams's quadrant, Cole's quadrant, Collins's or Sutton's quadrant, Davis's quadrant, Gunter's quadrant, Hadley's quadrant, the Horodictical quadrant, and the Sinical quadrant, &c. Of these, the two most deserving of notice, are Hadley's quadrant, and the mural or astronomical quadrant.

1. *The Common, or Surveying* QUADRANT, is the instrument the use of which may be seen in my Mensuration, in the section on heights-and-distances.

2. *The Astronomical* QUADRANT, is a large one, usually made of brass or iron bars; having its limb EF (fig.3 pl.29) accurately divided, either diagonally or otherwise, into degrees, minutes, and seconds, if room will permit, and furnished either with two pair of plain sights or two telescopes, one on the side of the quadrant at AB, and the other, CD, moveable about the centre by means of the screw G. The dented wheels I and H serve to direct the instrument to any object or phenomenon.—The application of this useful instrument, in taking observations of the sun, planets, and fixed stars, is obvious; for being turned horizontally on its axis, by means of the telescope AB, till the object is seen through the moveable telescope, then the degrees &c cut by the index, give the altitude &c required.

3. *Cole's* QUADRANT, is a very useful instrument, invented by Mr. Benjamin Cole. It consists of six parts, viz, the staff AB (fig.11, pl.29); the quadrantal arch DE; three vanes, A, B, C; and the vernier FG. The staff is a bar of wood about 2 feet long, an inch and a quarter broad, and of a sufficient thickness to prevent it from bending or warping. The quadrantal arch is also of wood; and is divided into degrees and 3d parts of degrees, to a radius of about 9 inches; and to its extremities are fitted two radii, which meet in the centre of the quadrant by a pin, about which it easily moves. The sight-vane A is a thin piece of brass, near 2 inches in height, and one broad, set perpendicularly on the end of the staff A, by means of two screws passing through its foot. In the middle of this vane is drilled a small hole, through which the coincidence or meeting of the horizon and solar spot is to be viewed. The horizon-vane B is about an inch broad, and two inches and a half high, having a slit cut through it of near an inch long, and a quarter of an inch broad; this vane is fixed in the centre pin of the instrument, in a perpendicular position, by means of two screws passing through its foot, by which its position with respect to the sight-vane is always the same, their angle of inclination being equal to 45 degrees. The shade-vane C is composed of two brass plates; one of which serves as an arm, and is about 4½ inches long, and ¾ of an inch broad, being pinned at one end to the upper limb of the quadrant by a screw, about which it has a small motion; the other end lies in the arch, and the lower edge of the arm is directed to the middle of the centre-pin: the other plate, which is properly the vane, is about 2 inches long, being fixed perpendicularly to the other plate, at about half an inch distance from that end next the arch; this vane may be used either by its shade, or by the solar spot cast by a convex lens placed in it. And because the wood-work is often subject to warp or twist, therefore this vane may be rectified by means of a screw, so that the warping of the instrument may occasion no error in the observation, which is performed in the following manner: Set the line G on the vernier against a degree on the upper limb of the quadrant, and turn the screw on the backside of the limb forward or backward, till the hole in the sight-vane, the centre of the glass, and the sunk spot in the horizon-vane, lie in a right line.

To find the Sun's Altitude by this instrument. Turn your back to the sun, holding the staff of the instrument with the right hand, so that it be in a vertical plane passing through the sun; apply one eye to the sight-vane, looking through that and the horizon-vane till the horizon be seen; with the left hand slide the quadrantal arch upwards, till the solar spot, or shade, cast by the shade-vane, fall directly upon the spot or slit in the horizon-vane; then will that part of the quadrantal arch, which is raised above G or S (according as the observation respects either the solar spot or shade) show the altitude of the sun at that time. But for the meridian altitude, the observation must be continued, and as the sun approaches the meridian, the sea will appear through the horizon-vane, which completes the observation; and the degrees and minutes, counted as before, will give the sun's meridian altitude: or the degrees counted from the lower limb upwards will give the zenith distance.

4. *Adams's* QUADRANT, differs only from Cole's, just described, in having an horizontal vane, with the upper part of the limb lengthened; so that the glass, which casts the solar spot on the horizon-vane, is at the same distance from the horizon-vane as the sight-vane at the end of the index.

5. *Collins's* or *Sutton's* QUADRANT, is a stereographic projection of one quarter of the sphere between the tropics, on the plane of the ecliptic, the eye being in its north pole; and fitted to the latitude of London. The lines running from right to left, are parallels of altitude; and those crossing them are azimuths. The smaller of the two circles, bounding the projection, is one quarter of the tropic of Capricorn; and the greater is a quarter of the tropic of Cancer. The two ecliptics are drawn from a point on the left edge of the quadrant, with the characters of the signs upon them; and the two horizons are drawn from the same point. The limb is divided both into degrees and time; and by having the sun's altitude, the hour of the day may here be found to a minute. The quadrantal arches next the centre contain the calendar of months; and under them, in another arch, is the sun's declination. On the projection are placed several of the most remarkable fixed stars between the tropics; and the next below the projection is the quadrant and line of shadows.

6. *Davis's* QUADRANT, the same as the BACKSTAFF; which see.

7. *Gunner's* QUADRANT, (fig. 6, pl. 29), sometimes called the *Gunner's Square*, is used for elevating and pointing cannon, mortars, &c, and consists of two branches either of wood or brass, between which is a quadrantal arch divided into 90°, and furnished with a thread and plummet.—The use of this instrument is very easy; for if the longer branch, or bar, be placed in the mouth of the piece and it be elevated till the plummet cut the degree necessary to hit a proposed object, the thing is done.—Sometimes on the sides of the longer bar,

are noted the division of diameters and weights of iron balls, as also the bores of pieces.

8. *Gunter's* QUADRANT, so called from its inventor Edmund Gunter (fig. 4, pl. 29) besides the apparatus of other quadrants, has a stereographic projection of the sphere on the plane of the equinoctial; and also a calendar of the months, next to the divisions of the limb; by which means, besides the common purposes of other quadrants, several useful questions in astronomy, &c, are easily resolved.

Use of Gunter's Quadrant.—(1) To find the sun's meridian altitude for any given day, or conversely the day of the year answering to any given meridian altitude. Lay the thread to the day of the month in the scale next the limb; then the degree it cuts in the limb is the sun's meridian altitude. And, contrariwise, the thread being set to the meridian altitude, it shows the day of the month.

(2) To find the hour of the day. Having set the bead, which slides on the thread, to the sun's place in the ecliptic, observe the sun's altitude by the quadrant; then if the bead be laid over the same in a limb, it will fall upon the hour required. On the contrary, laying the bead on a given hour, having first rectified or set it to the sun's place, the degree cut by the thread on the limb gives the altitude.—The bead may be rectified otherwise, by bringing the thread to the day of the month, and the bead to the hour-line of 12.

(3) To find the sun's declination from his place given; and the contrary. Bring the bead to the sun's place in the ecliptic, and move the thread to the line of declination ET, so shall the bead cut the degree of declination required. On the contrary, the bead being adjusted to a given declination, and the thread moved to the ecliptic, it will cut the sun's place.

(4) The sun's place being given, to find the right ascension; or the contrary. Lay the thread on the sun's place in the ecliptic, and the degree it cuts on the limb is the right ascension sought. And the converse.

(5) The sun's altitude being given, to find his azimuth; and the contrary. Rectify the bead for the time, as in the second article, and observe the sun's altitude; bring the thread to the complement of that altitude; then the bead will give the azimuth sought, among the azimuth-lines.

9. *Hadley's* QUADRANT, (fig. 7, pl. 29) so called from its inventor John Hadley, esq. is now universally used as the best of any for nautical and other observations. It seems the first idea of this excellent instrument was suggested by Dr. Hooke; for Dr. Sprat, in his History of the Royal Society, pa. 246, mentions the invention of a new instrument for taking angles by reflection, by which means the eye at once sees the two objects both as touching the same point, though distant almost to a semicircle; which is of great use for making exact observations at sea. This instrument is described and illustrated by a figure in Hooke's Posthumous Works, pa. 503. But as it admitted of only one reflection, it would not answer the purpose. The matter however was at last effected by Sir Isaac Newton, who communicated to Dr. Halley a paper of his own writing, containing the description of an instrument with two reflections, which soon after the doctor's death was found among his papers by Mr. Jones, by whom it was communicated to the Royal Society, and it was published in the Philos. Trans. for the year 1742. How it happened that Dr. Halley never mentioned this in his lifetime, is difficult to account for; more especially as Mr. Hadley had described, in the Transac. for 1731, his instrument, which is constructed on the same principles. Mr. Hadley, who was well acquainted with Sir Isaac Newton, might have heard him say, that Dr. Hooke's proposal could be effected by means of a double reflection; and perhaps in consequence of this hint, he might apply himself, without any previous knowledge of what Newton had actually done, to the construction of his instrument. Mr. Godfrey too, of Pennsylvania, had recourse to a similar expedient; for which reason some gentlemen of that colony have ascribed the invention of this excellent instrument to him. The truth may probably be, that each of these gentlemen discovered the method independent of one another. See Trans. of the American Society, vol. 1, pa. 21 Appendix.

This instrument consists of the following particulars: 1. An octant, or the 8th part of a circle, ABC. 2. An index D. 3. The speculum E. 4. Two horizontal glasses, F, G. 5. Two screens, K and K. 6. Two sight-vanes, H and I.—The octant consists of two radii, AB, AC, strengthened by the braces L, M, and the arch BC; which, though containing only 45°, is nevertheless divided into 90 primary divisions, each of which stands for degrees, and are numbered 0, 10, 20, 30, &c, to 90; beginning at each end of the arch for the convenience of numbering both ways, either for altitudes or zenith distances: also each degree is subdivided into minutes, by means of a vernier. But the number of these divisions varies with the size of the instrument.

The index D, is a flat bar, moveable about the centre of the instrument; and that part of it which slides over the graduated arch, BC, is open in the middle, with Vernier's scale on the lower part of it; and underneath is a screw, serving to fasten the index against any division.

The speculum E is a piece of flat glass, quicksilvered on one side, set in a brass box, and placed perpendicular to the plane of the instrument, the middle part of the former coinciding with the centre of the latter: and because the speculum is fixed to the index, the position of it will be altered by the moving of the index along the arch. The rays of an observed object are received on the speculum, and from thence reflected on one of the horizon glasses, F or G; which are two small pieces of looking-glass placed on one of the limbs, their faces being turned obliquely to the speculum, from which they receive the reflected rays of objects. The glass F has only its lower part silvered, and set in brass-work; the upper part being left transparent to view the horizon. The glass G has in its middle a transparent slit, through which the horizon is to be seen. And because the warping of the materials, and other accidents, may distend them from their true situation, there are three screws passing through their feet, by which they may be easily replaced.

The screens are two pieces of coloured glass, set in two square brass frames K, K, which serve as screens to take off the glare of the sun's rays, which would otherwise be too strong for the eye; the one is tinged much deeper than the other; as they both move on the same centre, they may be both or either of them used: in the situation they have in the figure, they serve for the horizon-glass F; but when they are wanted for the horizon-glass G, they must be taken from their present situation, and placed on the quadrant above G.

The sight-vanes are two pins, H and I, standing perpendicularly to the plane of the instrument: that at H having a hole in it, opposite to the transparent slit in the horizon-glass G; the other, at I, has two holes in it, the one opposite to the middle of the transparent part of the horizon-glass F, and the other rather lower than the quick-silvered part: this vane has a piece of brass on the back of it, which moves round a centre, and serves to cover either of the holes.

Of the Observations.—There are two kinds of observations to be made with this instrument: the one is when the back of the observer is turned towards the object, and therefore called the back observation; the other when his face is turned towards the object, which is called the fore-observation.

To Rectify the Instrument for the Fore-observation.—Slacken the screw in the middle of the handle behind the glass F; and bring the index close to the button *h*; hold the instrument in a vertical position, with the arch downwards; look through the right-hand hole in the vane I, and through the transparent part of the glass F, for the horizon; and if it lie in the same right line with the image of the horizon seen on the silvered part, the glass F is rightly adjusted; but if the two horizontal lines disagree, turn the screw which is at the end of the handle backward or forward, till those lines coincide; then fasten the middle screw of the handle, and the glass is rightly adjusted.

To take the Sun's Altitude by the Fore-observation.—Having fixed the screens above the horizon-glass F, and suited them proportionally to the strength of the sun's rays, turn your face towards the sun, holding the instrument with your right hand, by the braces L and M, in a vertical position, with the arch downward; place your eye close to the right-hand hole in the vane I, and view the horizon through the transparent part of the horizon-glass F, at the same time moving the index D with the left hand, till the reflex solar spot coincides with the line of the horizon; then the degrees counted from C, or that end next your body, will give the sun's altitude at that time, observing to add or subtract 16 minutes according as the upper or lower edge of the sun's reflex image is made use of.

But to get the sun's meridian altitude, being what is wanted for finding the latitude; the observations must be continued; and as the sun approaches the meridian, the index D must be continually moved towards B, to maintain the coincidence between the reflex solar spot and the horizon; and consequently as long as this motion can maintain the same coincidence, the observation must be continued, till the sun has reached the meridian, and begins to descend, when the coincidence will require a retrograde motion of the index, or towards C; then the observation is finished, and the degrees counted as before will give the sun's meridian altitude, or those from B will give the zenith distance; observing to add the semi-diameter, or 16′, when his lower edge is brought to the horizon; or to subtract 16′, when the horizon and upper edge coincide.

To take the Altitude of a Star by the Fore-observation.—Through the vane H, and the transparent slit in the glass G, look directly to the star; and at the same time move the index, till the image of the horizon behind you, being reflected by the great speculum, be seen in the silvered part of G, and meet the star; then will the index show the degrees of the star's altitude.

To Rectify the Instrument for the Back-observation.—Slacken the screw in the middle of the handle, behind the glass G; turn the button *h* on one side, and bring the index as many degrees before 0 as is equal to double the dip of the horizon at your height above the water; hold the instrument vertical, with the arch downward; look through the hole of the vane H; and if the horizon, seen through the transparent slit in the glass G, coincide with the image of the horizon seen in the silvered part of the same glass, then the glass G is in its proper position; but if not, set it by the handle, and fasten the screw as before.

To take the Sun's Altitude by the Back-observation.—Put the stem of the screens, K, K, into the hole *r*, and in proportion to the strength or faintness of the sun's rays, let either one or both or neither of the frames of those glasses be turned close to the face of the limb; hold the instrument in a vertical position, with the arch downward, by the braces L and M, with the left hand; then turn your back to the sun, and put one eye close to the hole in the vane H, observing the horizon through the transparent slit in the horizon glass G; with the right hand move the index D, till the reflected image of the sun be seen in the silvered part of the glass G, and in a right line with the horizon; swing your body to and fro, and if the observation be well made, the sun's image will be observed to brush the horizon, and the degrees reckoned from C, or that part of the arch furthest from your body, will give the sun's altitude at the time of observation; observing to add 16′, for the sun's semidiameter, if the sun's upper edge be used, or subtract the same for the lower edge.

The directions just given, for taking altitudes at sea, would be sufficient, but for two corrections that are necessary to be made before the altitude can be accurately determined, viz, one on account of the observer's eye being raised above the level of the sea, and the other on account of the refraction of the atmosphere, especially in small altitudes. The following tables show the corrections to be made on both these accounts.

TABLE I. Dip of the Horizon of the Sea.		TABLE II. Refractions of the Stars &c in Altitude.			
Height of the Eye.	Dip of the Horizon.	Appar. Altitude in Deg.	Refraction.	Appar. Altitude. in Deg.	Refraction.
Feet.					
1	0′ 57″	0°	33′ 0″	11°	4′ 47″
2	1 21	¼	30 35	12	4 23
3	1 39	½	28 22	15	3 30
5	2 8	1	24 29	20	2 35
10	3 1	2	18 35	25	2 2
15	3 42	3	14 36	30	1 38
20	4 16	4	11 51	35	1 21
25	4 46	5	9 54	40	1 8
30	5 14	6	8 29	45	0 57
35	5 39	7	7 20	50	0 48
40	6 2	8	6 29	60	0 33
45	6 24	9	5 48	70	0 21
50	6 44	10	5 15	80	0 10

General Rules for these Corrections.

1. In the fore-observations, add the sum of both corrections to the observed zenith distance, for the true zenith distance: or subtract the said sum from the observed altitude, for the true one. 2. In the back-observation, add the dip and subtract the refraction for altitudes; and for zenith distances, do the contrary, viz. subtract the dip, and add the refraction.

Example. By a back-observation, the altitude of the sun's lower edge was found by Hadley's quadrant to be 25° 12′; the eye being 30 feet above the horizon. By the tables the dip on 30 feet is 5′ 14″, and the refraction on 25° 12′ is 2′ 1″. Hence

Appar. alt. lower limb	25°	12′	0″
Sun's semidiameter, sub.	0	16	0
Appar. alt. of centre	24	56	0
Dip. of horizon, add	0	5	14
	25	1	14
Refraction, subtract	0	2	1
True alt. of centre	24	59	13

In the case of the moon, besides the true corrections above, another is to be made for her parallaxes. But for all these particulars, see the Requisite Tables for the Nautical Almanac, also Robertson's Navigation, vol. 2, pa. 340 &c, edit. 1780.

10. *Horodictical* QUADRANT, a pretty commodious instrument, which is so called from its use in telling the hour of the day. Its construction is as follows. From the centre of the quadrant C, (fig. 5, pl. 29), whose limb AB is divided into 90°, describe seven concentric circles at any intervals; and to these add the signs of the zodiac, in the order represented in the figure. Then, applying a ruler to the centre C and the limb AB, mark upon the several parallels the degrees corresponding to the altitude of the sun, when in them, for the given hours; connect the points belonging to the same hour with a curve line, to which add the number of the hour. To the radius CA fit a couple of sights, and to the centre of the quadrant C tie a thread with a plummet, and on the thread a bead to slide.

11. *Sinical* QUADRANT, is one of some use in Navigation. It consists of several concentric quadrantal arches, divided into 8 equal parts by means of radii, with parallel right lines crossing each other at right angles. Now any one of the arches may represent a quadrant of any great circle of the sphere, but is chiefly used for the horizon or meridian. The chief use of the sinical quadrant, is to form upon it triangles similar to those made by a ship's way with the meridians and parallels; the sides of which triangles are measured by the equal intervals between the concentric quadrants and the lines N and S, E and W: every 5th line and arch being made deeper than the rest. Now suppose a ship has sailed 150 leagues north-east-by-north, or making an angle of 33° 45′ with the north part of the meridian: here are given the course and distance sailed, by which a triangle may be formed on the instrument similar to that made by the ship's course; and hence the unknown parts of the triangle may be found.

Sutton's QUADRANT. See *Collins's* QUADRANT.

12. QUADRANT *of Altitude*, (fig. 9, pl. 29) is an appendix to the artificial globe, consisting of a thin slip of brass, the length of a quarter part of one of the great circles of the globe, and graduated. At the end, where the division terminates, is a nut riveted on, and furnished with a screw, by means of which the instrument is fitted on the meridian, and moveable round upon the rivet to all points of the horizon, as represented in the figure referred to. Its use is to serve as a scale in measuring altitudes, amplitudes, azimuths, &c.

QUADRANTAL *Triangle*, is a spherical triangle, which has one side equal to a quadrant or quarter part of a circle.

QUADRAT, called also *Geometrical Square*, and *Line of Shadows*: it is often an additional member on the face of Gunter's and Sutton's quadrants; and is chiefly useful in taking heights or depths. See my Mensuration, the chap. on altimetry and longimetry, or heights-and-distances.

QUADRATIC *Equations*, in Algebra, are those in which the unknown quantity is of two dimensions, or raised to the 2d power. Quadratic equations are either simple, or affected, that is compound.

A Simple QUADRATIC *equation*, is that which contains the 2d power only of the unknown quantity, without any other power of it; as $x^2 = 25$, or $y^2 = ab$. And in this case, the value of the unknown quantity is found by barely extracting the square root on both sides of the equation: thus, in the equations above, it will be $x = \pm 5$, and $y = \pm \sqrt{ab}$; where the sine of the root of the known quantity is to be taken either plus or minus, for either of these may be considered as the sign of the value of the root x, since either of them, when squared, make the same square, $(+5)^2 = 25$, and $(-5)^2 = 25$ also; and hence the root of every quadratic or square, has two values.

Compound or *affected* QUADRATICS, are those which contain both the 1st and 2d powers of the unknown quantity; as $x^2 + ax = b$, or $x^{2n} - ax^n = \pm b$, where n may be of any value, and then x^n is to be considered as the root or unknown quantity.—Affected quadratics are usually distinguished into three forms, according to the signs of the terms of the equation:

Thus, 1st form, $x^2 + ax = b$,
2d form, $x^2 - ax = b$,
3d form, $x^2 - ax = -b$.

But the method of extracting the root, or finding the value of the unknown quantity x, is the same in all of them. And that method is usually performed by what is called completing the square, which is done by taking half the coefficient of the 2d term or single power of the unknown quantity, then squaring it, and adding that square to both sides of the equation, which makes the unknown side a complete square. Thus, in the equation $x^2 + ax = b$, the coefficient of the 2d term being a, its half is $\frac{1}{2}a$, the square of which is $\frac{1}{4}a^2$, and this added to both sides of equation, it becomes $x^2 + ax + \frac{1}{4}a^2 + = \frac{1}{4}a^2 b$, the former side of which is now a complete square, and the scond a known quantity.

The square being thus completed, its root is next to be extracted; in order to which, it is to be observed that the root on the unknown side consists of two terms, the one of which is always x the square root of the first term of the equation, and the other part is $\frac{1}{2}a$ or half the coefficient of the second term: thus then the root of $x^2 + ax + \frac{1}{4}a^2$ the first side of the completed equation being $x + \frac{1}{2}a$, and the root of the other side $\frac{1}{4}a^2 + b$ being $\pm\sqrt{(\frac{1}{4}a^2 + b)}$, it follows that $x + \frac{1}{2}a = \pm\sqrt{(\frac{1}{4}a^2 + b)}$, and hence, by transposing $\frac{1}{2}a$, it is $x = -\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 + b)}$, the two values of x, or the roots of the given equation $x^2 + ax = b$. And thus is found the root, or value of x, in the three forms of equations above mentioned: viz,

$$\text{1st form } x = -\tfrac{1}{2}a \pm \sqrt{(\tfrac{1}{4}a^2 + b)},$$
$$\text{2d form } x = +\tfrac{1}{2}a \pm \sqrt{(\tfrac{1}{4}a^2 + b)},$$
$$\text{3d form } x = +\tfrac{1}{2}a \pm \sqrt{(\tfrac{1}{4}a^2 - b)}.$$

Where it is observable that, because of the double sign $\pm$, every form has two roots: in the 1st and 2d forms those roots are, the one positive and the other negative, the positive root being the less of the two in the 1st form, but the greater in the 2d form; and in the 3d form the roots are both positive. Again, the two roots of the 1st and 2d forms, are always both of them real; but in the 3d form, the two roots are either both real or both imaginary, viz, both real when $\frac{1}{4}a^2$ is greater than b, or both imaginary when $\frac{1}{4}a^2$ is less than b, because in this case $\frac{1}{4}a^2 - b$ will be a negative quantity, the root of which is impossible, or an imaginary quantity.

Example of the 1st form, let $x^2 + 6x = 7$. Here then $a = 6$, and $b = 7$; then $x = -\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 + b)} = -3 \pm \sqrt{16} = -3 \pm 4 = +1$ or -7.

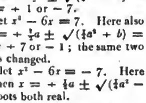
Example of the 2d form, let $x^2 - 6x = 7$. Here also $a = 6$, and $b = 7$; then $x = +\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 + b)} = +3 \pm \sqrt{16} = +3 \pm 4 = +7$ or -1; the same two roots as before, with the signs changed.

Example of the 3d form, let $x^2 - 6x = -7$. Here again $a = 6$, and $b = 7$; then $x = +\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 - b)} = +3 \pm \sqrt{2}$, the two roots both real.

But if $x^2 - 6x = -11$; then $a = 6$, and $b = 11$, which gives x or $+\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 - b)} = +3 \pm \sqrt{-2}$, the two roots both imaginary.

All equations whatever that have only two different powers of the unknown quantity, of which the index of the one is just double that of the other, are resolved like quadratics, by completing the square. Thus, the equation $x^4 + ax^2 = b$, by completing the square becomes $x^4 + ax^2 + \frac{1}{4}a^2 = \frac{1}{4}a^2 + b$; whence, extracting the root on both sides, $x^2 + \frac{1}{2}a = \pm\sqrt{(\frac{1}{4}a^2 + b)}$; therefore $x^2 = -\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 + b)}$, and consequently $x = \pm\sqrt{(-\frac{1}{2}a \pm \sqrt{(\frac{1}{4}a^2 + b)})}$, where the root x has four values, because the given equation $x^4 + ax^2 = b$ rises to the 4th power. See EQUATION.

QUADRATRIX, or QUADRATIX, in Geometry, is a mechanical line, by means of which, right lines are found equal to the circumference of circles, or other curves, and of the parts of the same. Or, more accurately, the quadratrix of a curve, is a transcendental curve described on the same axis, the ordinates of which being given, the quadrature of the correspondent parts in the other curve, is also given. See CURVE. Thus, for ex. the curve AND may be called the quadratrix of the parabola AMC, when the area



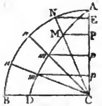
APMA bears some such relation as the following to the absciss AP or ordinate PN, viz,

when APM = PN^2,
or APM = AP × PN,
or APM = a × PN,

where a is some given constant quantity.

The most distinguished of these quadratices are, those of Dinostrates and of Tschirnhausen for the circle, and that of Mr. Perks for the hyperbola.

QUADRATRIX *of Dinostrates*, is a curve AMD, by which the quadrature of the circle is effected, though not geometrically, but only mechanically. It is so called from its inventor Dinostrates; and the genesis or description of which is as follows: Divide the quadrantal arc ANB into any number of equal parts, in the



points N, n, n, &c; and also the radius AC into the same number of parts at the points P, p, p, &c. To the points N, n, n, &c, draw the radii CN, Cn, &c; and from the points P, p, &c, the parallels to CB, as PM, Pm, &c: then through all the points of intersection draw the curve AMmD, and it will be the quadratrix of Dinostrates.

Or the same curve may be conceived to be described by a continued motion, by conceiving a radius CN to revolve with a uniform motion about the centre C, from the position AC to the position BC; at the same time a ruler PM moves uniformly parallel towards CB; then the two uniform motions being so regulated that the radius and the ruler shall arrive at the position BC at the same time; for thus the continual intersection M, m, &c. of the revolving radius, and moving ruler, will describe the quadratrix of Dinostrates. Hence,

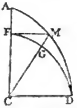
1. *For the Equation of the Quadratrix*: Since, from the relation of the uniform motions, it is always, AB : AN : : AC : AP; therefore if AB = a, AC = r, AP = x, and AN = z, it will be $a : z : : r : x$, or $ax = rz$, which is the equation of the curve.

Or, if s denote the sine NE of the arc AN, and y = PM the ordinate of the curve AM, its absciss AP being x; then, by similar triangles, CE : CP : : EN : PM, that is, $(r^2\sqrt{} - s^2) : r - x : : s : y$, and hence $y\sqrt{(r^2 - s^2)} = (r - x)s$, the equation of the curve. And when the relation between AB and AN is given, in terms of that between AC and AP, hence will be expressed the relation between the sine EN and the radius CB, or s will be expressed in terms of r and x; and consequently, the equation of the curve will be expressed in terms of r, x, and y only.

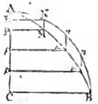
2. The base of the quadratrix CD is a third proportional to the quadrant AB and the radius AC or CB; i. e. CD : CB : : CB : AB. Hence the rectification and quadrature of the circle.

3. A quadrantal arc DF described with the centre C and radius CD, will be equal in length to the radius CA or CB.

4. CDF being a quadrant inscribed in the quadratrix AMD, if the base CD be = 1, and the circular arc DG = x; then is the area CFMD = $x - \frac{1}{9}x^3 - \frac{1}{225}x^5 - \frac{2}{6615}x^7$ &c. See QUADRATURE. Also Emerson's Curve Lines, pa. 16.



QUADRATRIX *of Tschirnhausen*, is a transcendental curve AMmB by which the quadrature of the circle is also effected. This was invented by M. Tschirnhausen, and its genesis, in imitation of that of Dinostrates, is as follows: Divide the quadrant ANB, and the radius AC,



each into equal parts, as before; and from the points P, p, &c, draw the lines PM, pm, &c, parallel to CB; also from the points N, n, &c, the lines NM, nm, &c, parallel to the other radius AC; so shall all the intersections M, m, &c, be in the curve of the quadratrix AMmB.

Now for the Equation of this Quadratrix; it is, as before, AB : AN : : AC : AP, or $a : z : : r : x$, or $ax = rz$.

Or, because here $y =$ PM $=$ RN $= s$; therefore s, as before, expressed in terms of r and x, gives the equation of this quadratrix in terms of r, x, and y, and that in a simpler form than the other. Thus, from the nature of the circle and the construction of the quadratrix, it is

$$y \text{ or } s = x + \frac{r^2 - x^2}{2 \cdot 3r^2}A + \frac{3^2r^2 - x^2}{4 \cdot 5r^2}B + \frac{5^2r^2 - x^2}{6 \cdot 7r^2}C \text{ \&c,}$$

where A, B, C, &c, are the preceding terms; which is the equation of the quadratrix of Tschirnhausen.

By either quadratrix, it is evident that an arc or angle is easily divided into three, or any other number of equal parts; viz, by dividing the corresponding radius, or part of it, into the same number of equal parts: for AN is always the same part of AB, that AP is of AC.

QUADRATURE, in Astronomy, that aspect or position of the moon when she is 90° distant from the sun. Or, the quadratures or quarters are the two middle points of the moon's orbit between the points of conjunction and opposition, viz, the points of the 1st and 3d quarters; at which times the moon's face shows half full, being dichotomized or bisected.

The moon's orbit is more convex in the quadratures than in the syzygies, and the greater axis of her orbit passes through the quadratures, at which points also she is most distant from the earth.—In the quadratures, and within 35° of them, the apses of the moon go backwards, or move in antecedentia; but in the syzygies the contrary.—When the nodes are in the quadratures, the inclination of the moon's orbit is greatest, but least when they are in the syzygies.

QUADRATURE *Lines*, or *Lines of* QUADRATURE, are two lines often placed on Gunter's sector. They are marked with the letter Q, and the figures 5, 6, 7, 8, 9, 10; of which Q denotes the side of a square, and the figures denote the sides of polygons of 5, 6, 7, &c sides. Also S denotes the semidiameter of a circle, and 90 a line equal to the quadrant or 90° in circumference.

QUADRATURE, in Geometry, is the squaring of a figure, or reducing it to an equal square, or finding a square equal to the area of it.—The quadrature of rectilineal figures falls under common geometry, or mensuration; as amounting to no more than the finding their areas, or superficies; which are in effect their squares: which was fully effected by Euclid.

The QUADRATURE *of Curves*, that is, the measuring of their areas, or the finding a rectilineal space equal to a proposed curvilineal one, is a matter of much deeper speculation; and makes a part of the sublime or higher geometry. The lunes of Hypocrates are the first curves that were squared, as far as we know. The circle was attempted by Euclid and others before him: he showed indeed the proportion of one circle to another, and gave a good method of approximating to the area of the circle, by describing a polygon between any two concentric circles, however near their circumferences might be to each other. At that time the conic sections were admitted into geometry, and Archimedes, perfectly, for the first time, squared the parabola, and he determined the relations of spheres, spheroids, and conoids, to cylinders and cones; and by pursuing the method of exhaustions, or by means of inscribed and circumscribed polygons, he approximated to the periphery and area of the circle; showing that the diameter is to the circumference nearly as 7 to 22, and the area of the circle to the square of the diameter as 11 to 14 nearly. Archimedes also determined the relation between the circle and ellipse, as well as that of their similar parts: and it is probable also that he attempted the hyperbola; but it is not likely that he met with any success, since approximations to its area are all that can be given by the various methods that have since been invented. Besides these figures, he left a treatise on a spiral curve; in which he determined the relation of its area to that of the circumscribed circle; as also the relation of their sectors.

Several other eminent men among the ancients wrote upon this subject, both before and after Euclid and Archimedes; but their attempts were usually confined to particular parts of it, and made according to methods not essentially different from theirs. Among these are to be reckoned Thales, Anaxagoras, Pythagoras, Bryson, Antiphon, Hippocrates of Chios, Plato, Apollonius, Philo, and Ptolemy; most of whom wrote upon the quadrature of the circle; and those after Archimedes, by his method, usually extended the approximation to a further degree of accuracy.

Many of the moderns have also prosecuted the same problem of the quadrature of the circle, after the same methods, to still greater lengths; such are Vieta, and Metius; whose ratio between the diameter and the circumference, is that of 113 to 355, which is within about $\frac{3}{10000000}$ of the true ratio; but above all, Ludolph van Ceulen, or Culogne, who, with an amazing degree of industry and patience, by the same methods, extended the ratio to 36 places of figures, making the ratio to be that of 1 to 3·14159, 26535, 89793, 23846, 26433, 83279, 50288 + or 9 −.

Of this labour, which was rather the exercise of patience than his ingenuity, he was so proud, that, after the example of the profound geometrician of Syracuse, with respect to the sphere and cylinder, he requested it might be inscribed on his tombstone, and it is said that this monument of his patient industry is still to be seen in one of the towns of Flanders. Willebrode Snell, the editor of Van Ceulen, also made several additions to what had been previously done on this subject. He discovered and published in his work, entitled Cyclometriæ, the method of expressing, by an approximate proportion, and a very simple calculation, the magnitude of any arc; and he made use of this method in examining the calculation of Van Ceulen, which he found to be correct. By this method he also calculated a series of both inscribed and circumscribed polygons, beginning with the decagon, and always doubling the number of sides, until the number was 5242880; and ranged the results of his computations in a table, for the purpose of detecting the falsity of any pretended quadrature of the circle. The celebrated Huygens, when very young, enriched this measure of the circle with several new theorems; and successfully combated the pretended quadrature of Gregory St. Vincent, a Jesuit of the Netherlands, who announced his discovery as only wanting a few calculations to render it complete, but which he dexterously forgot to perform. James Gregory and Leibnitz, about the same time, discovered, independent of each other, a very simple series for expressing the length of an arc of a circle, and which was first given in a letter of the 15th of February 1671, from Gregory to Mr. Collins. If a be an arc, t its tangent, and r the radius, then

$$a = t \times \left(1 - \frac{t^2}{3r^2} + \frac{t^4}{5r^4} - \frac{t^6}{7r^6} + \frac{t^8}{9r^8} - \&c\right).$$

But the arc must not be assumed greater than half a quadrant, otherwise the series will not converge. Dr. Halley also discovered a simple series for expressing the arc of 30°; which is,

$$a = \sqrt{\tfrac{1}{3}} \times \left(1 - \frac{1}{3.3} + \frac{1}{5.3^2} - \frac{1}{7.3^3} + \frac{1}{9.3^4} - \&c\right);$$

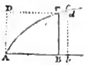
and which converges very quickly, and being multiplied by 12, gives the whole circumference. Mr. Sharp, an English mathematician, in 1699, undertook the quadrature of the circle for his own private amusement, and deduced it from two different series, by which the truth of it was proved to 72 places of figures. But Mr. John Machin, professor of astronomy in Gresham College, discovered another very expeditious series for expressing the length of the circumference of a circle, depending on the differences of arcs, the tangents of which have certain relations to each other, and thus extended Mr. Sharp's number to 100 places of figures. And M. De Lagny, a French mathematician, continued this computation to 128 places of figures; on which Montucla has observed, that, "if we suppose a circle, the diameter of which is a thousand millions of times greater than the distance between the sun and the earth, the error in the circumference would be a thousand millions of times less than the thickness of a hair." Nay, it is even possible to surpass this, and Euler has pointed out the method of accomplishing it, in the Transactions of the Imperial Academy of Sciences at Petersburg; but any thing farther than what has been done, could only be considered as superfluous labour. I have also given several series for the same purpose, which converge much easier and quicker than any others; some of which may be seen in my Mensuration, and more especially in my Tracts, vol. 1, pa. 268.

While these, and other mathematicians, were extending the approximative methods for finding the circumference and area of the circle, some were endeavouring to obtain, and even asserting that they had obtained, their true measures; at the same time others were denying the possibility of exhibiting the true ratio. Mr. James Gregory undertook, in 1668, to demonstrate the absolute impossibility of the quadrature of the circle. This he did by a very ingenious method of reasoning, which might deserve to be better examined. However it did not meet with the approbation of Mr. Huygens; which produced a very warm dispute between these two geometricians. Mr. Gregory gave also some ingenious methods for approaching near to the measure of the circle, and even to that of the hyperbola. Dr. Barrow and several other persons have also attempted the demonstration of the same impossibility, with various degrees of success. Of this latter opinion was the celebrated Dr. Barrow, who in his mathematical lecture, observes, that the radius and circumference of a circle are lines of such a nature as to be not only incommensurable in length and square, but also in cube, biquadrate, and all higher powers to infinity. But, notwithstanding the attempts of Dr. Barrow, and many other celebrated mathematicians, to prove the absolute impossibility of resolving this interesting problem, they have been as unsuccessful on this head as those who have endeavoured to find its true quadrature. Legendre, however, in the fourth note prefixed to his Geometry, has proved that the ratio of the circumference to the diameter, and its square, are irrational numbers. Besides the efforts above enumerated, which were made principally by men of great talents, many other vain attempts at squaring the circle have been made by men of less acquirements than vanity, who have endeavoured to persuade us that they had discovered the true quadrature of the circle, which so many able mathematicians had so long sought in vain; and whose pretensions, like falling stars, attracted notice for a moment, and then, like them, sank into eternal oblivion. The first among the moderns who pretended to have solved this problem, was Cardinal de Cusa. He rolled a cylinder over a plane, till the point which first was in contact with it touched it again; and then, by a train of reasoning, wholly destitute of geometrical precision, he endeavoured to determine the length of a line thus described; but he was easily refuted by Regiomontanus about 1465. Near a century after, Orontius Finæus attracted notice by his parallogisms on this subject; but the fallacy of his reasoning was clearly shown by Peter Nunez, and J. Borelli. The celebrated Joseph Scaliger also ranks under this class; who having no great esteem for geometricians, he endeavoured to show them his superiority, in undertaking, by way of amusement, the quadrature of the circle, and seriously imagined that he had obtained it; but Vieta, Clavius, and others, found no difficulty in refuting him. Longomontanus, the celebrated Danish astronomer, was also of the number who asserted he had obtained a finite ratio between the diameter and circumference, which was exactly 1 to 3·14185. And our countryman, Mr. Hobbes, also rendered himself remarkable as a member of this class, but his pretensions were refuted by Dr. Wallis. Oliver de Serres weighed a circle, and a triangle equal to the equilateral inscribed triangle, and believed that the one was exactly double of the others; but, a very little knowledge of the subject would have been sufficient to have shown him, that the double of this triangle is the hexagon inscribed in the same circle. It would be tedious and uninteresting to go through the history of all these pretended quadratures, the authors of which would at this day have been totally unknown, had they not erected a monument to their own ignorance and vanity, by attempting that which they were totally unacquainted with. We shall, however, for the amusement of the reader, furnish him with a few more anecdotes on this head, in order to show to what a degree of enthusiasm some have suffered themselves to be carried in their erroneous speculations. One Mathulon, who from being a manufacturer of stuffs at Lyons, commenced geometer, claimed the merit of having solved this problem, and deposited 1000 crowns as a reward for the person who should prove that his solution was not correct; which was done by M. Nicole, a member of the French Academy of Sciences, who gave the reward to the General Hospital at Lyons; and a similar circumstance happened some time afterwards: a Frenchman announced the quadrature of the circle, and challenged the whole world to refute him; and deposited 10,000 livres for any person who should do it. This grand problem he reduced to the mechanical process of dividing a circle into quadrants, and then turning these with their angles outwards, so as to form a square, which be asserted to be equal to the circle. Three persons claimed the reward, and the cause was tried at the Chatelet of Paris; but the judges thought a person's fortune ought not to be diminished on account of the error of his judgment, unless they were prejudicial to society: whereon the king decreed that the proposal should be void: and the Academy of Sciences recommended him to study the elements of geometry; but still he fancied that future ages would blush for the injustice that was done him. M. Le Rohberges de Vausenville, in a work, entitled, "Consultation sur la Quadrature du Cercle," inquires of a mathematician if the quadrature of the circle would not be obtained if any means were devised for finding the centre of gravity of a sector of a circle in common parts of the radius and the circumference of the same circle; the meaning of this last clause is not clear, but it may be observed that when this can be done without the arc being one of the terms, the business will be accomplished.

The preceding examples, one might suppose, would be sufficient for deterring men from farther pursuing this hopeless speculation; yet such is the weakness and vanity of some pretenders to science, that hopes are still entertained by them of obtaining the solution within very narrow limits. We have an instance of this infatuation in Signor Rossi, an Italian attorney, who visited London about five years ago, to claim the reward of his ingenuity in squaring the circle; but, unfortunately, it rested upon the supposition that the side of a square is to its diagonal as 5 to 7, or in other words that 49 is equal to 50; he was, notwithstanding, very much dissatisfied at not receiving the reward he fancied himself entitled to, and returned with a perfect conviction that the English had not done him justice. See my Translation of Montucla's Recreations, vol. 1, pa. 299, &c, 2d edition.

But though a definite quadrature of the whole circle was never yet given, nor of any aliquot part of it; yet certain other portions of it have been squared. The first partial quadrature was given by Hippocrates of Chios; who squared a portion called, from its figure, the Lune, or Lunule; but this quadrature has no dependence on that of the circle. And some modern geometricians have found the quadrature of any portion of the lune taken at pleasure, independently of the quadrature of the circle; though still subject to a certain restriction, which prevents the quadrature from being perfect, and what the geometricians call absolute and indefinite. See LUNE. And for the quadrature of the different kinds of curves, see their several particular names.

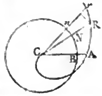
QUADRATURES, *by Fluxions*.—The most general method of quadratures yet discovered, is that of Newton, by means of fluxions, and is as follows. AC being any curve to be squared, AB an absciss, and BC an ordinate perpendicular to it, also *bc* another ordinate indefinitely near to the former. Putting AB $= x$, and BC $= y$; then is B$b = \dot{x}$ the fluxion of the abscis, and $y\dot{x} =$ Cb the fluxion of the area ABC sought. Now let the value of the ordinate y be found in terms of the abscis x, or in a function of the abscis, and let that function be called X, that is $y =$ X; then substituting X for y in $y\dot{x}$, gives X$\dot{x}$ the fluxion of the area; and the fluent of this, being taken, gives the area or quadrature of ABC as required, for any curve, whatever its nature may be.



Ex. Suppose, for example, AC to be a common parabola; then its equation is $px = y^2$, where p is the parameter; which gives $y = \sqrt{px}$, the value of y in a function of x, and is what is called X above; hence then $y\dot{x} = \dot{x}\sqrt{px} = p^{\frac{1}{2}}x^{\frac{1}{2}}\dot{x}$ is the fluxion of the area; and the fluent of this is $\frac{2}{3}p^{\frac{1}{2}}x^{\frac{3}{2}} = \frac{2}{3}x\sqrt{px} = \frac{2}{3}xy = \frac{2}{3}$ of the circumscribing rectangle BD; which therefore is the quadrature of the parabola.

Again, if AC be a circle whose diameter is d; then its equation is $y^2 = dx - x^2$, which gives $y = \sqrt{(dx-x^2)}$, and the fluxion of the area $y\dot{x} = \dot{x}\sqrt{(dx-x^2)}$. But as the fluent of this cannot be found in finite terms, the quantity $\dot{\sqrt{}}(dx-x^2)$ is developed or thrown into a series, and then the fluxion of the area is $y\dot{x} = \dot{x}\sqrt{(dx-x^2)}$ $= \dot{x}\sqrt{dx} \times (1 - \frac{x}{2d} - \frac{x^2}{2.4d^2} - \frac{1.3x^3}{2.4.6d^3}$ &c); and the fluent of this gives $x\sqrt{dx} \times$ $(\frac{2}{3} - \frac{1}{5} \cdot \frac{x}{d} - \frac{1}{4.7} \cdot \frac{x^2}{d^2} - \frac{1.3}{4.6.9} \cdot \frac{x^3}{d^3}$ &c) for the general expression of the area ABC. Now when the space becomes a semicircle, x becomes $= d$, and then the series above becomes $d^2(\frac{2}{3} - \frac{1}{5} - \frac{1}{4.7} - \frac{1.3}{4.6.9}$ &c) for the area of the semicircle whose diameter is d.

In spirals CAR, or any curves referred to a centre C; putting $y =$ any radius CR, $x =$ BN the arc of a circle described about the centre C, at any distance CB $= a$, and Cnr another ray indefinitely near CNR: then $\frac{1}{2}$CN . N$n = \frac{1}{2}a\dot{x} =$ CNn, and by sim. fig. CN^2 : CR^2 or $a^2 : y^2$: : CNn : $\frac{y^2\dot{x}}{2a} =$ CRr the fluxion of the area described by the revolving ray CR; then the fluent of this, for any particular case, will be the quadrature of the spiral. So if, for instance, it be Archimedes's spiral, in which x : y in a constant ratio, suppose as $m : n$, or $my = nx$, and $y^2 = \frac{n^2x^2}{m^2}$; hence then CR$r = \frac{y^2\dot{x}}{2a} = \frac{n^2x^2\dot{x}}{2am^2}$ the fluxion of the area; the fluent of which is $\frac{n^2x^3}{6am^2} = \frac{xy^2}{6a}$, the general quadrature of the spiral of Archimedes.



QUADRIBLE. Squarable.

QUADRILATERAL, or QUADRILATERAL *Figure*, is a figure comprehended by four right lines; and having consequently also four angles; for which reason it is otherwise called a quadrangle. The general term quadrilateral comprehends these several particular species of figures, viz, the square, parallelogram, rectangle, rhombus, rhomboides, and trapezium. If the opposite sides be parallel, the quadrilateral is a parallelogram. If the parallelogram have its angles right ones, it is a rectangle; if oblique, it is an oblique one. The rectangle having all its sides equal, becomes a square; and the oblique parallelogram having all its sides equal, is a rhombus, but if only the opposites be equal, it is a rhomboides. All other forms of the quadrilateral, are trapeziums, including all the irregular shapes of it.

The sum of all the four angles of any quadrilateral, is equal to 4 right angles. Also, the two opposite angles of a quadrilateral inscribed in a circle, taken together, are equal to two right angles. And in this case the rectangle of the two diagonals is equal to the sum of the two rectangles of the opposite sides. For the properties of the particular species of quadrilaterals, see their respective names, SQUARE, RECTANGLE, PARALLELOGRAM, RHOMBUS, RHOMBOIDES, TRAPEZIUM, and TRAPEZOID.

QUADRIPARTITION, is the dividing by 4, or into four equal parts.

QUADRUPLE, is four-fold, or something taken four times, or multiplied by 4.

QUALITY, denotes generally the property or affection of some being, by which it affects our senses in a certain way, &c.

Sensible QUALITIES are such as are the more immediate object of the senses: as figure, taste, colour, smell, hardness, &c.

Occult QUALITIES, among the ancients, were such as did not admit of a rational solution in their way.

Dr. Keil demonstrates, that every quality which is propagated in orbem, such as light, heat, cold, odour, &c, has its efficacy or intensity either increased, or decreased, in a duplicate ratio of the distances from the centre of radiation inversely. So at double the distance from the earth's centre, or from a luminous or hot body, the weight or light or heat, is but a 4th part; and at 3 times the distance, they are 9 times less, or a 9th part, &c.

Sir Isaac Newton lays it down as one of the rules of philosophizing, that those qualities of bodies that are incapable of being intended and remitted, and which are found to obtain in all bodies on which experiment could ever be tried, are to be esteemed universal qualities of all bodies.

QUALITY *of Curvature*, in the higher Geometry, is used to signify its form, as it is more or less inequable, or as it is varied more or less in its progress through different parts of the curve. Newton's Method of Fluxions, pa. 75; and Maclaurin's Fluxions, art. 369.

QUANTITY, denotes any thing capable of estimation, or mensuration; or which, being compared with another thing of the same kind, may be said to be either greater or less, equal or unequal to it. Mathematics is the doctrine or science of quantity.

Physical or *Natural* QUANTITY, is of two kinds: 1st, that which nature exhibits in matter, and its extension; and 2dly, in the powers and properties of natural bodies; as gravity, motion, light, heat, cold, density, &c. Quantity is popularly distinguished into continued and discrete.

Continued QUANTITY, is when the parts are connected together, and is commonly called magnitude; which is the object of geometry.

Discrete QUANTITY, is when the parts, of which it consists, exist distinctly, and unconnected; which makes what is called multitude or number, the object of arithmetic.

The notion of continued quantity, and its difference from discrete, appears to some without foundation. Mr. Machin considers all mathematical quantity, or that for which any symbol is put, as nothing else but number, with regard to some measure, which is considered as 1; for that we know nothing precisely how much any thing is, but by means of number. The notion of continued quantity, without regard to some measure, is indistinct and confused; and though some species of such quantity, considered physically, may be described by motion, as lines by the motion of points, and surfaces by the motion of lines; yet the magnitudes, or mathematical quantities, are not made by the motion, but by numbering according to a measure. Philos. Trans. numb. 447, pa. 228.

QUANTITY *of Action*. See ACTION.

QUANTITY *of Curvature* at any point of a curve is determined by the circle of curvature at that point, and is reciprocally proportional to the radius of curvature.

QUANTITY *of Matter* in any body, is its measure arising from the joint consideration of its magnitude and density, being expressed by, or proportional to the product of the two. So,

if M and m denote the magnitude of two bodies,
and D and d their densities;
then DM and dm will be as their quantities of matter.

The quantity of matter of a body is best discovered by its absolute weight, to which it is always proportional, and by which it is measured.

QUANTITY *of Motion*, or the *Momentum*, of any body, is its measure arising from the joint consideration of its quantity, and the velocity with which it moves. So,

if q denote the quantity of matter,
and v the velocity of any body;
then qv will be its quantity of motion.

QUANTITIES, in Algebra, are the expressions of indefinite numbers, that are usually represented by letters. Quantities are properly the subject of algebra; which consists in the computation of such quantities.

Algebraic quantities are either given and known, or else they are unknown and sought. The given or known quantities are usually represented by the first letters of the alphabet, as a, b, c, d, e, &c, and the unknown or required quantities, by the last letters, as z, y, x, w, &c. and also indeterminate, or such as may be assumed at pleasure, by some of the middle letters, as m, n, p, &c.

Again, algebraic quantities are either positive or negative.—A positive or affirmative quantity, is one that is to be added, and has the sign $+$ or plus prefixed, or understood; as ab or $+ab$. And a negative or privative quantity, is one that is to be subtracted, and has the sign $-$ or minus prefixed; as $-ab$.

QUART, a measure of capacity, being the quarter or 4th part of some other measure. The English quart is the 4th part of the gallon, and contains two pints. The Roman quart, or quartarius, was the 4th part of their congius. The French had, besides their quart or pot of two pints, various other quarts, distinguished by the whole of which they are quarters; as quart de muid, and quart de boisseau.

QUARTER, the 4th part of a whole, or one part of an integer, which is divided into four equal portions.

QUARTER, in weights, is the 4th part of the quintal, or hundred weight; and so contains 28 pounds.

QUARTER is also a dry measure, containing of corn 8 bushels striked; and of coals the 4th part of a chaldron.

QUARTER, in Astronomy; the moon's period, or lunation, is divided into 4 stages or quarters, each containing between 7 and 8 days. The first quarter is from the new moon to the quadrature; the second is from thence to the full moon, and so on.

QUARTER, in Navigation, is the quarter or 4th part of a point, wind, or rhumb; or of the distance between two points &c. The quarter contains an arch of 2° 48′ 45″, being the 4th part of 11° 15′, which is one point.

QUARTER *Round*, in Architecture, is a term used by the workmen for any projecting moulding, whose contour is a quarter of a circle, or nearly so.

QUARTILE, an aspect of the planets when they are at the distance of 3 signs or 90° from each other: and is denoted by the character □.

QUEUE D'ARONDE, or *Swallow's Tail*, in Fortification, is a detached or outwork, whose sides spread or open towards the campaign, or draw narrower and closer towards the gorge. Of this kind are either single or double tenailles, and some horn-works, whose sides are not parallel, but are narrow at the gorge, and open at the head, like the figure of a swallow's tail. On the contrary, when the sides are less than the gorge, the work is called contre Queue d'aronde.

QUEUE *d'Aronde*, in Carpentry, a method of jointing, called also dove-tailing.

QUICKSILVER, the same as MERCURY; which see.

QUINCUNX, in Astronomy, is that position, or aspect, of the planets, when distant from each other by $\frac{5}{12}$ths of the whole circle, or 5 signs out of the 12, that is 150 degrees. The quincunx is marked Q, or Vc.

QUINDECAGON, is a plane figure of 15 sides, and consequently the same number of angles. When those are all equal, it is a regular quindecagon, otherwise not. Euclid shows how to inscribe this figure in a circle, prop. 16, lib. 4. And the side of a regular quindecagon, so inscribed, is equal in power to the half difference between the side of the equilateral triangle, and the side of the pentagon; and also the difference of the perpendiculars let fall on both sides, taken together.

QUINQUAGESIMA-*Sunday*, is the same as Shrove-Sunday, and is so called as being about the 50th day before Easter, being indeed the 7th Sunday before it. Anciently the term quinquagesima was used for Whitsunday, and for the 50 days between Easter and Whitsunday; but to distinguish this quinquagesima from that before Easter, it was called the paschal quinquagesima.

QUINQUEANGLED, or QUINQUEANGULAR, consisting of 5 angles.

QUINTAL, the weight of a hundred pounds, in most countries; but in England it is the hundred weight, or 112 pounds. Quintal was also formerly used for a weight of lead, iron, or other common metal, usually equal to a hundred pounds, at 6 score to the hundred.

QUINTILE, in Astronomy, an aspect of the planets when they are distant the 5th part of the zodiac, or 72 degrees; and is marked thus, c, or o.

QUINTUPLE, 5 times as much as another thing.

QUOIN, in Architecture, an angle or corner of stone or brick walls. When these stand out beyond the rest of the wall, their edges being chamferred off, they are called rustic quoins.

QUOIN, in Artillery, is a loose wedge of wood, which is put in below the breech of a cannon, to raise or depress it more or less.

QUOTIENT, in Arithmetic, is the result of the operation of division, or the number that arises by dividing the dividend by the divisor, showing how often the latter is contained in the former. Thus the quotient of 12 divided by 3 is 4; which is usually thus disposed, or expressed, 3) 12 (4 the quotient, or thus $12 \div 3 = 4$ the quotient, or thus $\frac{12}{3}$, like a vulgar fraction; all these meaning the same thing.—In division, as the divisor is to the dividend, so is unity or 1 to the quotient; thus 3 : 12 : : 1 : 4 is the quotient.

R.

RADIANT *Point*, or RADIATING *Point*, is any point from which rays proceed. Every radiant point diffuses innumerable rays in all directions: but those rays are only visible from which right lines can be drawn to the pupil of the eye; because the rays are all in right lines. All the rays proceeding from the same radiant continually diverge; but the crystalline collects or reunites them again.

RADIATION, is the casting or shooting forth of rays of light as from a centre.—Every visible body is a radiating body; it being only by means of its rays that it affects the eye.—The surface of a radiating or visible body, may be conceived as consisting of radiant points.

RADICAL *Sign*, in Algebra, the sign or character denoting the root of a quantity; and is this, $\sqrt{}$. So $\sqrt{2}$ is the square root of 2, and $\sqrt[3]{2}$ is the cube root of 2, &c.

RADIOMETER, a name which some writers give to the radius astronomicus, or Jacob's staff. See FORE-STAFF.

RADIUS, in Geometry, the semidiameter of a circle; or a right line drawn from the centre to the circumference.—It is implied in the definition of a circle, and it is apparent from its construction, that all the radii of the same circle are equal.—The radius is sometimes called, in trigonometry, the sinus totus, or whole sine.

RADIUS, in the Higher Geometry. RADIUS *of the Evoluta*, RADIUS *Osculi*, called also the *Radius of concavity*, and the *Radius of curvature*, is the right line CB, representing a thread, by whose evolution from off the curve AC, upon which it was wound, the curve AB is formed. Or it is the radius of a circle having the same curvature, in a given point of the curve at B, with that of the curve in that point. See CURVATURE and EVOLUTE, where the method of finding this radius may be seen.

RADIUS *Astronomicus*, an instrument usually called Jacob's staff, the Cross-staff, or Fore-staff.

RADIUS, in Mechanics, is applied to the spokes of a wheel; because issuing like rays from its centre.

RADIUS, in Optics. See RAY.

RADIUS *Vector*, is used for a right line drawn from the centre of force in any curve in which a body is supposed to move by a centripetal force, to that point of the curve where the body is supposed to be. In the elliptical orbit of a planet, let a = the greater semiaxis; ae = distance from the centre to the focus, or e = excentricity for the greater semiaxis 1, v = true anomaly, and u = excentric anomaly; then the radius vector r is expressed by either of the following formulæ, $r = a(1 + e \cos. u)$ or $r = \frac{a(1-e^2)}{1-e \cos. v}$.

RADIX, or *Root*, is a certain finite expression or function, which, being evolved or expanded according to the rules proper to its form, produces a series. That finite expression, or radix, is also the value of the infinite series. So $\frac{1}{3}$ is the radix of ·3333 &c, because $\frac{1}{3}$ being evolved or expanded, by dividing 1 by 3, gives the infinite series ·3333 &c. In like manner, the radix

of $1 - r + r^2 - r^3 + r^4$ &c is $\frac{1}{1+r}$,

of $1 - \frac{1}{2} + \frac{1}{4} - \frac{1}{8} + \frac{1}{16}$ &c is $\frac{1}{1+\frac{1}{2}}$,

of $1 - 1 + 1 - 1 + 1$ &c is $\frac{1}{1+1}$,

of $1 - 2 + 4 - 8 + 16$ &c is $\frac{1}{1+2}$,

of $\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32}$ &c is $\frac{1}{2+1}$,

of $1 + x + x^2 + x^3 + x^4$ &c is $\frac{1}{1-x}$,

of $1 + 2x + 3x^2 + 4x^3 + 5x^4$ &c is $\frac{1}{(1-x)^2}$,

of $1 + \frac{x^2}{2} + \frac{3x^4}{8} + \frac{5x^6}{16} + \frac{35}{128}x^8$ &c is $\sqrt{\frac{1}{1-x^2}}$.

See my Tracts, vol. 1, tracts 7 and 8.

RAFTERS, in Architecture, are pieces of timber which stand by pairs on the raising-piece, or wall plate, and meet in an angle at the top, forming the roof of a building. These commonly rise at 45°, and meet in a right angle at top; and then the roof is said to be of a true pitch.

RAIN, water that descends from the atmosphere in the form of drops of a considerable size. Rain is apparently a precipitated cloud; as clouds are nothing but vapours raised from moisture, waters, &c. By this circumstance it is distinguished from dew and fog: in the former of which the drops are so small that they are quite invisible; and in the latter, though their size be larger, they seem to have very little more specific gravity than the atmosphere itself, and may therefore be reckoned hollow spherules rather than drops.

It is universally agreed, that rain is produced by the water previously absorbed by the heat of the sun, or otherwise, from the terraqueous globe, into the atmosphere, as vapours, or vesiculæ. These vesiculæ, being specifically lighter than the atmosphere, are buoyed up by it, till they arrive at a region where the air is in a just balance with them; and there they float, till by some new agent they are converted into clouds, and thence either into rain, snow, hail, mist, or the like.

But the agent in this formation of the clouds into rain, and even of the vapours into clouds, has been much controverted. Most philosophers will have it, that the cold, which constantly occupies the superior regions of the air, chills and condenses the vesiculæ, at their arrival from a warmer quarter; congregates them together, and occasions several of them to coalesce into little masses: and thus their quantity of matter increasing in a higher proportion than their surface, they become an overload to the thin air, and so descend in rain.

Dr. Derham accounts for the precipitation, from the vesiculæ being full of air; when they meet with a colder air than that they contain, this is then contracted into a less space: and consequently the watry shell or case becomes thicker, so as to become heavier than the air, &c.

But this separation cannot be ascribed to cold, since rain often takes place in very warm weather. And though we should suppose the condensation owing to the cold of the higher regions, yet there is a remarkable fact which will not allow us to have recourse to this supposition: for it is certain that the drops of rain increase in size considerably as they descend. On the top of a hill for instance, they will be small and inconsiderable, forming only a drizzling shower; but half way down the hill it is much more considerable; and at the bottom the drops will be very large, descending in an impetuous rain. Which shows that the atmosphere condenses the vapours as well where it is warm as where it is cold.

Others allow the cold only a part in the action, attributing to the wind a considerable part of the agency: alleging, that a wind blowing against a cloud will drive its vesiculæ upon one another, by which means several of them coalescing as before, will be enabled to descend; and that the effect will be still more considerable, if two opposite winds blow together towards the same place: they add, that clouds already formed, happening to be aggregated by fresh accessions of vapour continually ascending, may thence be enabled to descend.

Yet the grand cause, according to Rohault, is still behind. That author conceives it to be the heat of the air, which, after continuing for some time near the earth, is at length carried up on high by a wind, and there thawing the snowy villi or flocks of the half-frozen vesiculæ, it reduces them into drops; which, coalescing, descend, and have their dissolution perfected in their progress through the lower and warmer stages of the atmosphere.

Others, as Dr. Clarke, &c, ascribe this descent of the clouds rather to an alteration of the atmosphere than of the vesiculæ; and suppose it to arise from a diminution of the spring or elastic force of the air. This elasticity, which depends chiefly or wholly on the dry terrene exhalations, being weakened, the atmosphere sinks under its burden; and the clouds fall, on the common principle of precipitation.

Now the small vesiculæ, by these or any other causes, being once upon the descent, will continue to descend notwithstanding the increase of resistance they every moment meet with in their progress through still denser and denser parts of the atmosphere. For as they all tend toward the same point, viz, the centre of the earth, the farther they fall, the more coalitions will they make; and the more coalitions, the more matter will there be under the same surface; the surface only increasing as the squares, but the solidity as the cubes of the diameters: and the more matter under the same surface, the less friction or resistance there will be to the same matter.

Thus then, if the causes of rain happen to act early enough to precipitate the ascending vesiculæ, before they are arrived at any considerable height, the coalitions being few in so short a descent, the drops will be proportionably small; thus forming what is called dew. If the vapours prove more copious, and rise a little higher, there is produced a mist or fog. A little higher still, and they produce a small rain, &c. If they neither meet with cold nor wind enough to condense or dissipate them; they form a heavy, thick, dark sky, which lasts sometimes several days, or even weeks.

But later writers on this part of philosophical science have, with greater show of truth, considered rain as an electrical phenomenon. Signior Beccaria counts rain, hail, and snow, among the effects of a moderate electricity in the atmosphere. Clouds that bring rain, he thinks are produced in the same manner as thunder clouds, only by a moderate electricity. He describes them at large; and the resemblance which all their phenomena bear to those of thunder clouds, is very striking. He notes several circumstances attending rain without lightning, which render it probable that it is produced by the same cause as when it is accompanied with lightning. Light has been seen among the clouds by night in rainy weather; and even by day rainy clouds are sometimes seen to have a brightness evidently independent of the sun. The uniformity with which the clouds are spread, and with which the rain falls, he thinks are evidences of a uniform cause like that of electricity. The intensity also of electricity in his apparatus usually corresponded very nearly to the quantity of rain that fell in the same time. Sometimes all the phenomena of thunder, lightning, hail, rain, snow, and wind, have been observed at one time; which shows the connection they all have with some common cause. Signior Beccaria therefore supposes that, previous to rain, a quantity of electric matter escapes out of the earth, in some place where there is a redundancy of it; and in its ascent to the higher regions of the atmosphere, collects and conducts into its path a great quantity of vapours. The same cause that collects, will condense them more and more; till, in the places of the nearest intervals, they come almost into contact, so as to form small drops; which, uniting with others as they fall, come down in the form of rain. The rain will be heavier in proportion as the electricity is more vigorous, and the cloud approaches more nearly to a thunder cloud: &c. See Lettere dell Elettricismo; and Priestley's Hist. &c of Electricity, vol. 1, pa. 427, &c, 8vo. And for further accounts of the phenomena of rain, &c, see BAROMETER, EVAPORATION, OMBROMETER, PLUVIAMETER, VAPOUR, &c. See also the Theory of Rain, by Dr. James Hutton, art 2, vol. 1, of Transactions of the Royal Society of Edinburgh.

Quantity of RAIN. As to the general quantity of rain that falls, with its proportion in several places at the same time, and at the same place in different times, there are many observations, journals, &c, in the Philos. Trans., the Memoirs of the French Academy, &c.

It has been ascertained by observation, that the mean annual quantity of rain is greatest at the equator, where it decreases gradually towards the poles. Thus, at

Granada, Antilles,	lat. 12°	it is	126 inches.
St. Domingo	19 46′	-	120
Calcutta	22 23	-	81
Rome	41 54	-	39
England	33 00	-	32
Petersburg	59 16	-	16

Philos. Mag. vol 44, pa. 350. Hence it appears that the quantity of rain is influenced generally by the heat of the climate. But it is also much influenced by particular local causes and circumstances, as affected by hills and mountains, and by the vicinity of seas, &c, as further appears by the following tables and observations. Thus on measuring the rain that falls annually, its depth, on a medium, in several places, is found as in the following table:

Mean Annual Depth of Rain for several Places.

At	*Observed by*	*Inch.*
Townley, in Lancas.	Mr. Townley	42½
Upminster, in Essex	Dr. Derham	19¼
Zurich, Swisserland	Dr. Scheuchzer	32¼

See also the Meteorological Journal of the Royal Society, published annually in the Philos. Trans. and the article PLUVIAMETER or OMBROMETER.

It is reasonably to be expected, and all experience shows, that the most rain falls in places near the sea coast, and less and less as the places are situated more inland. Some differences also arise from the circumstances of hills, valleys, &c. So when the quantity of rain fallen in one year at London, is 20 inches, that on the western coast of England will often be twice as much, or 40 inches, or more. Those winds also bring most rain, that blow from the quarter in which is the most and nearest sea; as our west and south-west winds.

It is also found, by the pluviameter or rain-gage, that, in any one place, the more rain is collected in the instrument, as it is placed nearer the ground; without any appearance of a difference, between two places, on account of their difference of level above the sea, provided the instrument is but as far from the ground at the one place as at the other. These effects are remarked in the Philos. Trans. for 1769 and 1771, the former by Dr. Heberden, and the latter by Mr. Daines Barrington. Dr. Heberden says, "A comparison having been made between the quantity of rain, which fell in two places in London, about a mile distant from one another, it was found, that the rain in one of them constantly exceeded that in the other, not only every month, but almost every time that it rained. The apparatus used in each of them was very exact, and both made by the same artist; and upon examining every probable cause, this unexpected variation did not appear to be owing to any mistake, but to the constant effect of some circumstance, which not being supposed to be of any moment, had never been attended to. The rain-gage in one of these cases was fixed so high, as to rise above all the neighbouring chimneys; the other was considerably below them; and there appeared reason to believe, that the difference of the quantity of rain in these two places, was owing to this difference in the placing of the vessel in which it was received. A funnel was therefore placed above the highest chimneys, and another on the ground of the garden belonging to the same house, and there was found the same difference between these two, though placed so near one another, which there had been between them, when placed at similar heights in different parts of the town. After this fact was sufficiently ascertained, is was thought proper to try whether the difference would be greater at a much greater height; and a rain-gage was therefore placed upon the square part of the roof of Westminster Abbey. Here the quantity of rain was observed for a twelvemonth, the rain being measured at the end of every month, and care being taken that none should evaporate by passing a very long tube of the funnel into a bottle through a cork, to which it was exactly fitted. The tube went down very near to the bottom of the bottle, and therefore the rain which fell into it would soon rise above the end of the tube, so that the water was no-where open to the air except for the small space of the area of the tube: and by trial it was found that there was no sensible evaporation through the tube thus fitted up.—The following table shows the result of these observations.

From July the 7th 1766, to July the 7th 1767, there fell in a rain-gage, fixed

1766.	Below the top of a house.	Upon the top of a house.	Upon Westminster Abbey.
From the 7th to	Inches.	Inches.	Inches.
the end of July	3·591	3·210	2·311
August	0·558	0·479	0·508
September	0·421	0·344	
October	2·364	2·061	1·416
November	1·079	0·842	0·632
December	1·612	1·258	0·994
1767, January	2·071	1·455	1·035
February	2·864	2·494	1·335
March	1·807	1·303	0·587
April	1·437	1·213	0·994
May	2·432	1·745	1·142
June	1·997	1·426	1·145
July 7	0·395	0·309	
	22·608	18·139	12·099

By this table it appears, that there fell below the top of a house above a fifth part more rain, than what fell in the same space above the top of the same house; and that there fell upon Westminster Abbey not much above one half of what was found to fall in the same space below the tops of the houses. This experiment has been repeated in other places with the same result. What may be the cause of this extraordinary difference, has not yet been discovered; but it may be useful to notice it, in order to prevent that error, which would frequently be committed in comparing the rain of two places without attending to this circumstance."

Such were the observations of Dr. Heberden on first announcing this circumstance, viz, of different quantities of rain falling at different heights above the ground. Two years afterwards, Daines Barrington Esq. made the following experiments and observations, to show that this effect, with respect to different places, respected only the several heights of the instrument above the ground at those places, without regard to any real difference of level in the ground at those places.

Mr. Barrington caused two other rain-gages, exactly like those of Dr. Heberden, to be placed, the one upon mount Rennig, in Wales, and the other on the plane below, at about half a mile's distance, the perpendicular height of the mountain being 450 yards, or 1350 feet; each gage being at the same height above the surface of the ground at the two stations.

The results of the experiment are as below:

1770.	Bottom of the mountain.	Top of the mountain.
	Inches.	Inches.
From July 6 to 16	0·709	0·648
July 16 to 29	2·135	2·124
July 29 to Aug. 10.	0·610	0·656
Sept. 9 both bottles had run over.		
Sept. 9 to 30	3·234	2·464
Oct. 17. both bottles had run over.	-	
Oct. 17 to 22	0·747	0·885
Oct. 22 to 29	1·281	1·388
Nov. 20 both bottles were broken by the frost.	8·766	8·165

"The inference to be drawn from these experiments," Mr. Barrington observes, "seems to be, that the increase of the quantity of rain depends upon its nearer proximity to the earth, and scarcely at all on the height of places, provided the rain-gages are fixed at about the same distance from the ground.

"Possibly also a much controverted point between the inhabitants of mountains and plains may receive a solution from these experiments; as in an adjacent valley, at least, very nearly the same quantity of rain appears to fall within the same period of time as on the neighbouring mountains."

Dr. Heberden also adds the following note. "It may not be improper to subjoin to the foregoing account, that, in places where it was first observed, a different quantity of rain would be collected, according as the rain-gages were placed above or below the tops of the neighbouring buildings; the rain-gage below the top of the house, into which the greater quantity of rain had for several years been found to fall, was above 15 feet above the level of the other rain-gage, which in another part of London was placed above the top of the house, and into which the lesser quantity always fell. This difference therefore does not, as Mr. Barrington justly remarks, depend on the greater quantity of atmosphere, through which the rain descends: though this has been supposed by some, who have thence concluded that this appearance might readily be solved by the accumulation of more drops, in a descent, through a great depth of atmosphere."

The quantity of rain that falls at Bombay is very extraordinary. The following register of the quantity fallen there in 8 successive years, is extracted from the Monthly Magazine for 1796, pa. 99.

Gen. yearly average	63·85

From this abstract it appears, that the rainy season commences about the beginning of June, and ends in the 2d week of October; and that July is the most rainy month, the general average of July being 22·7 inches, or above one-third of the whole. The heaviest rain that fell during these 8 years, was in 1782, on July 19, 6 inches, 20th, 5·6, 21st 6·4.

RAINBOW, *Iris*, or simply the *Bow*, is a meteor in form of a party-coloured arch, or semicircle, exhibited in a rainy sky, opposite to the sun, by the refraction and reflection of his rays in the drops of falling rain. There is also a secondary, or fainter bow, usually seen investing the former at some distance. Among naturalists, we also read of lunar rainbows, marine rainbows, &c.

The rainbow, Sir Isaac Newton observes, never appears but where it rains in the sunshine; and it may be represented artificially, by contriving water to fall in small drops like rain, through which the sun shining, exhibits a bow to the spectator placed between the sun and the drops, especially if there be disposed beyond the drops some dark body, as a black cloth, or such like.

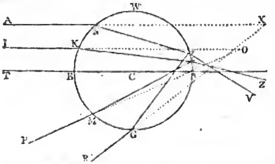
Some of the ancients, as appears by Aristotle's tract on Meteors, knew that the rainbow was caused by the refraction of the sun's light in drops of falling rain. Long afterwards, one Fletcher of Breslaw, in a treatise which he published in 1571, endeavoured more particularly to account for the colours of the rainbow by means of a double refraction, and one reflection. But he imagined that a ray of light, after entering a drop of rain, and suffering a refraction, both at its entrance and exit, was afterwards reflected from another drop, before it reached the eye of the spectator. It seems he overlooked the reflection at the farther side of the drop, or else he imagined that all the bendings of the light within the drop would not make a sufficient curvature, to bring the ray of the sun to the eye of the spectator. But Antonio de Dominis, Bishop of Spalato, about the year 1590, whose treatise De Radiis Visûs et Lucis was published in 1611 by J. Bartolus, first advanced, that the double refraction of Fletcher, with an intervening reflection, was sufficient to produce the colours of the rainbow, and also to bring the rays that formed them to the eye of the spectator, without any subsequent reflection. He distinctly describes the progress of a ray of light entering the upper part of the drop, where it suffers one refraction, and after being by that thrown upon the back part of the inner surface, is from thence reflected to the lower part of the drop; at which place undergoing a second refraction, it is thereby bent so as to come directly to the eye. To verify this hypothesis, he procured a small globe of solid glass, and viewing it when it was exposed to the rays of the sun, in the same manner in which he had supposed the drops of rain were situated with respect to them, he actually observed the same colours which he had seen in the true rainbow, and in the same order. Thus this author showed how the interior bow is formed in round drops of rain, viz, by two refractions of the sun's rays and one reflection between them; and he likewise showed that the exterior bow is formed by two refractions and two sorts of reflections between them in each drop of water.

The theory of A. de Dominis was adopted, and in some degree improved with respect to the exterior bow, by Descartes, in his treatise on Meteors; and indeed he was the first who, by applying mathematics to the investigation of this surprising appearance, ever gave a tolerable theory of the rainbow. Philosophers were however still at a loss when they endeavoured to assign reasons for all the particular colours, and for the order of them. Indeed nothing but the doctrine of the different refrangibility of the rays of light, a discovery which was reserved for the great Newton, could furnish a complete solution of this difficulty.

Dr. Barrow, in his Lectiones Opticæ, at Lect. 12, n. 14, says, that a friend of his (by whom we are to understand Mr. Newton) communicated to him a method of determining the angle of the rainbow, which was hinted to Newton by Slusius, without making a table of the refractions, as Descartes did. The doctor shows the method; as also several other matters, at n. 14, 15, 16, relating to the rainbow, worthy the genius of those two eminent men. But the subject was given more perfectly by Newton afterwards, viz, in his Optics, prop. 9; where he makes the breadth of the interior bow to be nearly 2° 15′, that of the exterior 3° 40′, their distance 8° 25′, the greatest semidiameter of the interior bow 42° 17′, and the least of the exterior 50° 42′, when their colours appear strong and perfect.

The doctrine of the rainbow may be illustrated and confirmed by experiment, in several different ways. Thus, by hanging up a glass globe, full of water, in the sunshine, and viewing it in such a posture that the rays which come from the globe to the eye, may include an angle either of 42° or 50° with the sun's rays; for ex. if the angle be about 42°, the spectator will see a full red colour in that side of the globe opposite to the sun. And by varying the position so as to make that angle gradually less, the other colours, yellow, green, and blue, will appear successively, in the same side of the globe, and that very bright. But if the angle be made about 50°, suppose by raising the globe, there will appear a red colour in that side of the globe towards the sun, though somewhat faint; and if the angle be made greater, as by raising the globe still higher, this red will change successively to the other colours, yellow, green, and blue. And the same changes are observed by raising or depressing the eye, while the globe is at rest. Newton's Optics, pt. 2, prop. 9, prob. 4.

Again, a similar bow is often observed among the waves of the sea (called the marine rainbow), the upper parts of the waves being blown about by the wind, and so falling in drops. This appearance is also seen by moonlight (called the lunar rainbow), though seldom vivid enough to render the colours distinguishable. Also it is sometimes seen on the ground, when the sun shines on a very thick dew. Cascades and fountains too, whose waters are in their fall divided into drops, exhibit rainbows to a spectator, if properly situated during the time of the sun's shining; and even water blown violently out of the mouth of an observer, standing with his back to the sun, never fails to produce the same phenomenon. The artificial rainbow may even be produced by candlelight on the water which is ejected by a small fountain or jet d'eau. All these are of the same nature, and they depend on the same causes; some account of which is as follows.

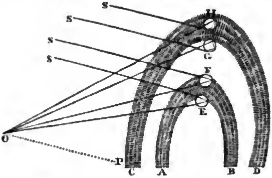


Let the circle WQOB represent a drop of water, or a globe, upon which a beam of parallel light falls, of which let TB represent a ray falling perpendicularly at B, and which consequently either passes through without refraction, or is reflected directly back from Q: suppose another ray IK, incident at K, at a distance from B; then this will be refracted according to a certain ratio of the sines of incidence and refraction to each other, which in rain water is as 529 to 396, to a point L, whence it will be in part transmitted in the direction LZ and in part reflected to M, where it will again in part be reflected, and in part transmitted in the direction MP, being inclined to the line described by the incident ray in the angle TOP. Another ray AN, still farther from B, and consequently incident under a greater angle, will be refracted to a point F, still farther from Q, whence it will be in part reflected to G, from which place it will in part emerge, forming an angle AXR with the incident AN, greater than that which was formed between the ray MP and its incident ray. And thus, while the angle of incidence, or distance of the point of incidence from B, increases, the distance between the point of reflection and Q, and the angle formed between the incident and emergent reflected rays, will also increase; that is, as far as it depends on the distance from B: but as the refraction of the ray tends to carry the point of reflection towards Q, and to diminish the angle formed between the incident and emergent reflected ray, and that the more the greater the distance of the point of incidence from B, there will be a certain point of incidence between B and W, with which the greatest possible distance between the point of reflection and Q, and the greatest possible angle between the incident and emergent reflected ray, will correspond. So that a ray incident nearer to B shall, at its emergence after reflection, form a less angle with the incident, by reason of its more direct reflection from a point nearer to Q; and a ray incident nearer to W, shall at its emergence form a less angle with the incident, by reason of the greater quantity of the angles of refraction at its incidence and emergence. The rays which fall for a considerable space in the vicinity of that point of incidence with which the greatest angle of emergence corresponds, will, after emerging, form an angle with the incident rays differing insensibly from that greatest angle, and consequently will proceed nearly parallel to each other; and those rays which fall at a distance from that point will emerge at various angles, and consequently will diverge. Now, to a spectator, whose back is turned towards the radiant body, and whose eye is at a considerable distance from the globe or drop, the divergent light will be scarcely, if at all, perceptible; but if the globe be so situated, that those rays that emerge parallel to each other, or at the greatest possible angle with the incident, may arrive at the eye of the spectator, he will, by means of those rays, behold it nearly with the same splendour at any distance.

In like manner, those rays which fall parallel on a globe, and are emitted after two reflections, suppose at the points F and G, will emerge at H parallel to each other, when the angle they make with the incident AN is the least possible; and the globe must be seen very resplendent when its position is such, that those parallel rays fall on the eye of the spectator.

The quantities of these angles are determined by calculation, the proportion of the sines of incidence and refraction to each other being known. And this proportion being different in rays which produce different colours, the angles must vary in each. Thus it is found, that the greatest angle in rain water for the least refrangible, or red rays, emitted parallel after one reflection, is 42° 2′, and for the most refrangible or violet rays, emitted parallel after one reflection, 40° 17′; likewise, after two reflections, the least refrangible, or red rays, will be emitted nearly parallel under an angle of 50° 57′, and the most refrangible, or violet, under an angle of 54° 7′; and the intermediate colours will be emitted nearly parallel at intermediate angles.

Suppose now, that O is the spectator's eye, and OP a line drawn parallel to the sun's rays, SE, SF, SO, and SH; and let POE, POF, POG, POH be angles of 40° 17′, 42° 2′, 50° 57′, and 54° 7′ respectively; then these angles turned about their common side OP, will with their other sides OE, OF, OG, OH, describe the verges of the two rainbows,



as in the figure. For, if E, F, G, H be drops placed any where in the conical superficies described by OE, OF, OG, OH, and be illuminated by the sun's rays SE, SF, SG, SH; the angle SEO being equal to the angle POE, or 40° 17′, will be the greatest angle in which the most refrangible rays can, after one reflection, be refracted to the eye, and therefore all the drops in the line OE must send the most refrangible rays most copiously to the eye, and so strike the sense with the deepest violet colour in that region. In like manner, the angle SFO being equal to the angle POF, or 42° 2′, will be the greatest in which the least refrangible rays after one reflection can emerge out of the drops, and therefore those rays must come most copiously to the eye from the drops in the line OF, and strike the sense with the deepest red colour in that region. And, by the same argument, the rays which have the intermediate degrees of refrangibility will come most copiously from drops between E and F, and strike the senses with the intermediate colours in the order which their degrees of refrangibility require; that is, in the progress from E to F, or from the inside of the bow to the outside, in this order, violet, indigo, blue, green, yellow, orange, red. But the violet, by the mixture of the white light of the clouds, will appear faint, and inclined to purple.

Again, the angle SGO being equal to the angle POG, or 50° 57′, will be the least angle in which the least refrangible rays can, after two reflections, emerge out of the drops, and therefore the least refrangible rays must come most copiously to the eye from the drops in the line OG, and strike the sense with the deepest red in that region. And the angle SHO being equal to the angle POH, or 54° 7′, will be the least angle in which the most refrangible rays, after two reflections, can emerge out of the drops, and therefore those rays must come most copiously to the eye from the drops in the line OH, and strike the sense with the deepest violet in that region. And, by the same argument, the drops in the regions between G and H will strike the sense with the intermediate colours in the order which their degrees of refrangibility require; that is, in the progress from G to H, or from the inside of the bow to the outside, in this order, red, orange, yellow, green, blue, indigo, and violet. And since the four lines OE, OF, OG, OH, may be situated any where in the above-mentioned conical superficies, what is said of the drops and colours in these lines, is to be understood of the drops and colours every where in those superficies.

Thus there will be made two bows of colours, an interior and stronger, by one reflection in the drops, and an exterior and fainter by two; for the light becomes fainter by every reflection; and their colours will lie in a contrary order to each other, the red of both bows bordering upon the space GF, which is between the bows. The breadth of the interior bow, EOF, measured across the colours, will be 1° 15′, and the breadth of the exterior GOH, will be 3° 10′, also the distance between them GOF, will be 8° 55′, the greatest semidiameter of the innermost, that is, the angle POF, being 42° 2′, and the least semidiameter of the outermost POG being 50° 57′. These are the measures of the bows as they would be, were the sun but a point; but by the breadth of his disc, the breadth of the bows will be increased by half a degree, and their distance diminished by as much; so that the breadth of the inner bow will be 2° 15′, that of the outer 3° 40′, their distance 8° 25′; the greatest semidiameter of the interior bow 42° 17′, and the least of the exterior 50° 42′. And such are the dimensions of the bows in the heavens found to be, very nearly, when their colours appear strong and perfect.

The light which comes through drops of rain by two refractions without any reflection, ought to appear strongest at the distance of about 26 degrees from the sun, and to decay gradually both ways as the distance from the sun increases and decreases. And the same is to be understood of light transmitted through spherical hailstones. If the hail be a little flatted, as it often is, the light transmitted may grow so strong at a little less distance than that of 26°, as to form a halo about the sun and moon; which halo, when the stones are duly figured, may be coloured, and then it must be red within, by the least refrangible rays, and blue without, by the most refrangible ones.

The light which passes through a drop of rain after two refractions, and three or more reflections, is scarce strong enough to cause a sensible bow.

As to the dimension of the rainbow, Descartes first determined its diameter by a tentative and indirect method; laying it down, that the magnitude of the bow depends on the degree of refraction of the fluid; and assuming the ratio of the sine of incidence to that of refraction, to be in water as 250 to 187. But Dr. Halley, in the Philos. Trans. number 267, gave a simple direct method of determining the diameter of the rainbow from the ratio of the refraction of the fluid being given; or, vice versa, the diameter of the rainbow being given, to determine the refractive power of the fluid. And Dr. Halley's principles and construction were further explained by Dr. Morgan, master of Clare Hall, Cambridge, in his Dissertation on the Rainbow, among the notes upon Rohault's System of Philosophy, part 3, chap. 17.

From the theory of the rainbow, all the particular phenomena of it are easily deducible. Hence we see, 1st, Why the iris is always of the same breadth; because the intermediate degrees of refrangibility of the rays between red and violet, which are its extreme colours, are always the same.

2dly, Why the bow shifts its situation as the eye does; and, according to the popular phrase, flies from those who follow it, and follows those that fly from it; the coloured drops being disposed under a certain angle, about the axis of vision, which is different in different places: whence also it follows, that every different spectator sees a different bow.

3dly, Why the bow is sometimes a larger portion of a circle, sometimes a less: its magnitude depending on the greater or less part of the surface of the cone, above the surface of the earth, at the time of its appearance; and the higher the sun is, the less will be the rainbow.

4thly, Why the bow never appears when the sun is above a certain altitude; the surface of the cone, in which it should be seen, being lost in the ground at a little distance from the eye, when the sun is above 42° high.

5thly, Why the bow never appears greater than a semicircle, on a plane; since, be the sun never so low, and even in the horizon, the centre of the bow is still in the line of aspect; which in this case runs along the earth, and is not at all raised above the surface. Indeed if the spectator be placed on a very considerable eminence, and the sun in the horizon, the line of aspect, in which the centre of the bow is, will be considerably raised above the horizon. And if the eminence be very high, and the rain near, it is possible the bow may be an entire circle.

6thly, How the bow may chance to appear inverted, or the concave side turned upwards; viz, a cloud happening to intercept the rays, and prevent their shining on the upper part of the arch: in which case, only the lower part appearing, the bow will seem as if turned upside down; which has probably been the case in several prodigies of this kind, related by authors.

Lunar RAINBOW. The moon sometimes also exhibits the phenomenon of an iris, by the refraction of her rays in the drops of rain in the night-time. Aristotle says, he was the first that ever observed it; and adds, it is never seen but at the time of the full moon; her light at other times being too faint to affect the sight after two refractions and one reflection. The lunar iris has all the colours of the solar, very distinct and pleasant; only fainter, both from the different intensity of the rays, and the different disposition of the medium.

Marine RAINBOW. This is a phenomenon sometimes observed in a much agitated sea; when the wind, sweeping part of the tops of the waves, carries them up; so that the sun's rays, falling upon them, are refracted, &c, as in a common shower, and there paint the colours of the bow. These bows are less distinguishable and bright than the common bow: but then they exceed as to numbers, there being sometimes 20 or 30 seen together. They appear at noon day, and in a position opposite to that of the common bow, the concave side being turned upwards, as indeed it ought to be.

RAIN-GAGE, an instrument for measuring the quantity of rain that falls. It is the same as OMBROMETER, or PLUVIAMETER; which see.

RAKED *Table*, or RAKING *Table*, in Architecture, a member hollowed in the square of a pedestal.

RAM, in Astronomy. See ARIES,

RAM, *Battering*. See BATTERING *Ram*.

RAMS-HORNS, in Fortification, a name given by Belidor to the tenailles.

RAMPART, or RAMPIER, in Fortification, a massy bank or elevation of earth around a place, to cover it from the direct fire of an enemy, and of sufficient thickness to resist the efforts of their cannon for many days. It is formed into bastions, curtains, &c.

Upon the rampart the soldiers continually keep guard, and the pieces of artillery are planted for defence. Also, to shelter the men from the enemy's shot, the outside of the rampart is built higher than the rest, i. e. a parapet is raised upon it with a platform. It is encompassed with a moat or ditch, out of which is dug the earth that forms the rampart, which is raised sloping, that the earth may not slip down, and having a berme at bottom, or is otherwise fortified, being lined with a facing of brick or stone.

The height of the rampart need not be more than 3 fathoms, this being sufficient to cover the houses from the battery of the cannon; neither need its thickness be more than 10 or 12, unless more earth come out of the ditch than can otherwise be bestowed.—The ramparts of halfmoons are the better for being low, that the small fire of the defendants may the better reach the bottom of the ditch; yet they must be so high as not to be commanded by the covert-way.

RAMPART is also used, in civil architecture, for the void space left between the wall of a city and the houses. This is what the Romans called Pomœrium, where it was forbidden to build, and where they planted rows of trees for the people to walk and amuse themselves under.

RAMSDEN (JESSE), F. R. S. an excellent optician and mechanist, was born at Halifax in Yorkshire, 1730; and died at Brighthelmstone, Nov. 5, 1800. He served his apprenticeship in his native place, to the trade of a hot-presser; after which, about 1751, he came to London, and applied himself to engraving. In the course of this employment, mathematical instruments were often brought to him to be engraved, which induced him to try his genius in that way; and with such success, that by the year 1763 he made instruments for several of the best artists. Soon after his coming up to London, he married the daughter of Mr. Dollond, the celebrated optician in St. Paul's Church-yard; by which means he was introduced to the knowledge of a profession in which his genius enabled him to excel, and attract the approbation of the public, in the same manner as his private worth endeared him to society. In 1763 he opened a shop in the Haymarket; but in 1775 he removed to Piccadilly, where he carried on business till his death.

Mr. R. greatly improved Hadley's quadrant, or sextant; and he invented a curious machine for dividing mathematical instruments; for which discovery he received a premium from the board of longitude. He also improved the construction of the theodolite, as well as the barometer for measuring the heights of mountains. The pyrometer for measuring the dilatation of bodies by heat, also employed his talents; and he made many important discoveries and improvements in optics. But his astronomical instruments appear to have been the principal of his works. He improved the refracting micrometer, as also the transit instrument and quadrant. He procured a patent for an improved equatorial. His mural quadrants were excellent, and much sought for.—Mr. Ramsden was chosen a fellow of the Royal Society in 1786.—Being always of a slender frame of body, as well as of delicate constitution, in his latter years his health gradually declined; to recruit which, he had retired to Brighthelmstone, where he died as before observed.

RAMUS (PETER), a celebrated French mathematician and philosopher, was born in 1515, in a village of Vermandois in Picardy. He was descended of a respectable family, which had been reduced to extreme poverty by the wars and other misfortnnes. His own life too, says Bayle, was the sport of fortune. In his infancy he was twice attacked by the plague. At an early age, a thirst for learning urged him to go to Paris; but he was soon forced by poverty to leave that city. He returned to it again as soon as he could; but, being unable to support himself, he left it a second time; yet his passion for study was so violent, that notwithstanding his bad success in the two former visits, he ventured on a third. He was maintained there some months by one of his uncles; after which he was obliged to become a servant in the college of Navarre. Here he spent the day in waiting on his masters, and the greatest part of the night in study.

After having finished classical learning and rhetoric, he went through a course of philosophy, which took him up three years and a half in the schools; but the thesis, which he made for his master-of-arts degrees, offended every one; for he maintained in it, that all that Aristotle had advanced was false; and he gave very good answers to the objections of the professors. This success encouraged him to examine the doctrine of Aristotle more closely, and to combat it vigorously: but he confined himself chiefly to his logic. The two first books he published, the one entitled, Institutiones Dialecticæ, the other Aristotelicæ Animadversiones, occasioned great disturbances in the university of Paris. The professors there, who were adorers of Aristotle, ought to have refuted Ramus's books, if they could, by writings and lectures: but instead of confining themselves within the just bounds of academical wars, they prosecuted this anti-peripatetic before the civil magistrate, as a man who was going to sap the foundations of religion. They raised such clamours, that the cause was carried before the parliament of Paris: but, perceiving that it would be examined equably, his enemies by their intrigues took it from that tribunal, to bring it before the king's council, in 1543. The king ordered, that Ramus and Anthony Govea, who was his principal adversary, should choose two judges each, to pronounce on the controversy, after they should have ended their disputation: while he himself appointed a deputy. Ramus appeared before the five judges, though three of them were his declared enemies. The dispute lasted two days, and Govea had all the advantages he could desire; Ramus's books being prohibited in all parts of the kingdom, and their author sentenced not to teach philosophy any longer; upon which his enemies triumphed in the most indecent manner.

The year after, the plague made great havoc in Paris, and forced most of the students in the college of Presle to quit it; but Ramus, being prevailed on to teach in it, soon drew together a great number of auditors. The Sorbonne attempted in vain to drive him from that college; for he held the headship of that house by arrêt of parliament: and through the patronage and protection of the cardinal of Lorrain, he obtained from Henry the 2d, in 1547, the liberty of speaking and writing, and the regal professorship of philosophy and eloquence in 1551. The parliament of Paris had, before this, maintained him in the liberty of joining philosophical lectures to those of eloquence; and this arrêt or decree had put an end to several prosecutions, which Ramus and his pupils had suffered. As soon as he was made regius professor, he was fired with a new zeal for improving the sciences, notwithstanding the hatred of his enemies, who were never at rest.

Ramus bore at that time a part in a very singular affair. About the year 1550, the royal professors corrected, among other abuses, that which had crept into the pronunciation of the Latin tongue. Some of the clergy followed this regulation; but the Sorbonnists were much offended at it as an innovation, and defended the old pronunciation with great zeal. Things at length were carried so far, that a minister, who had a good living, was very ill treated by them; and caused to be ejected from his benefice for having pronounced *quisquis, quanquam*, according to the new way, instead of *kiskis, kankam*, according to the old. The minister applied to the parliament; and the royal professors, with Ramus among them, fearing he would fall a victim to the credit and authority of the faculty of divines, for presuming to pronounce the Latin tongue according to their regulations, thought it incumbent on them to assist him. They accordingly went to the court of justice, and represented in such strong terms the indignity of the prosecution, that the minister was cleared, and every person had the liberty of pronouncing as he pleased.

Ramus was bred up in the Catholic religion, but afterwards deserted it. He first began to discover his new principles by removing the images from the chapel of his college of Presle, in 1552. On this account such a persecution was raised against him by the religionists, as well as Aristotelians, that he was driven out of his professorship, and obliged to conceal himself. For that purpose, with the king's leave he went to Fontainbleau; where, by the help of books in the king's library, he prosecuted geometrical and astronomical studies. As soon as his enemies found out his retreat, they renewed their persecutions; and he was forced to conceal himself in several other places. In the mean time, his curious and excellent collection of books in the college of Presle was plundered: but after a peace was concluded in 1563, between Charles the 9th and the Protestants, he again took possession of his employment, maintained himself in it with vigour, and was particularly zealous in promoting the study of the mathematics.

This continued till the second civil war in 1567, when he was forced to leave Paris, and shelter himself among the Hugonots, in whose army he was at the battle of St. Denys. Peace having been concluded some months after, he was restored to his professorship; but, foreseeing that the war would soon break out again, he did not care to venture himself in a fresh storm, and therefore obtained the king's leave to visit the universities of Germany. He accordingly undertook this journey in 1568, and received great honours wherever he came. He returned to France, after the third war in 1571; and lost his life miserably, in the massacre of St. Bartholomew's day, 1572, at 57 years of age. It is said, that he was concealed in a granary during the tumult; but discovered and dragged out by some peripatetic doctors who hated him; who, after stripping him of all his money under pretence of preserving his life, gave him up to the assassins, who, after cutting his throat and giving him many wounds, threw him out of the window; and his bowels gushing out in the fall, some Aristotelian scholars, encouraged by their masters, spread them about the streets; then dragged his body in a most ignominious manner, and threw it into the river.

Ramus was a great orator, a man of universal learning, and endowed with very fine qualities. He was sober, temperate, and chaste. He ate but little, and that of boiled meat; and drank no wine till the latter part of his life, when it was prescribed by the physicians. He lay upon straw; rose early, and studied hard all day; and led a single life with the utmost purity. He was zealous for the protestant religion, but at the same time a little obstinate, and given to contradiction. The protestant ministers did not love him much, for he made himself a kind of head of a party, to change the discipline of the protestant churches: his design was to introduce a democratical government in the church, but this design was traversed, and defeated in a national synod. His sect flourished however for some time afterwards, spreading pretty much in Scotland and England, and still more in Germany.

He published a great many books; but mathematics was chiefly obliged to him. Of this kind, his writings were principally these following:

1. Scholarum Mathematicarum libri 31.

2. Arithmeticæ libri duo—Algebræ libri duo.—Geometriæ libri 27.

These were greatly enlarged and explained by Schoner, and published in 2 volumes 4to. There were several editions of them; mine is that of 1627, at Frankfort.—The geometry, which is chiefly practical, was translated into English by William Bedwell, and published in 4to, at London, 1636.

3. He published also a singular book on geometry, being the 15 books of Euclid; containing only the definitions, and general enunciations of the propositions, without diagrams or demonstrations. In a kind of preface, he says he thinks it better for the teacher to suppress these. Paris, 1558, 4to, fol. 44.

RANDOM-SHOT, is a shot discharged with the axis of the gun elevated above the horizontal or point-blank direction.

RANDOM, of a shot, also sometimes means the range of it, or the distance to which it goes at the first graze, or where it strikes the ground. See RANGE.

RANGE, in Gunnery, sometimes means the path a shot flies in. But more usually

RANGE means the distance to which the shot flies when it strikes the ground or other object, called also the amplitude of the shot. But range is the term in present use.

Were it not for the resistance of the air, the greatest range, on a horizontal plane, would be when the shot is discharged at an angle of 45° above the horizon; and all other ranges would be the less, the more the angle of elevation is above or below 45°; but so as that at equal distances above and below 45°, the two ranges are equal to each other. But, on account of the resistance of the air, the ranges are altered, and that in different proportions, both for the different sizes of the shot, and their different velocities: so that the greatest range, in practice, always lies below the elevation of 45°, and the more below it as the shot is smaller, and as its velocity is greater; thus the smallest balls, discharged with the greatest velocity in practice, range the farthest with an elevation of 30° or under, while the largest shot, with very small velocities, range farthest with nearly 45° elevation; and at all the intermediate degrees in the other cases. See PROJECTILES.

RARE, in Physics, is the quality of a body that is very porous, whose parts are at a great distance from one another, and which contains but little matter under a great magnitude. In which sense rare stands opposed to dense.

The corpuscular philosophers, viz, the Epicureans, Gassendists, Newtonians, &c, assert that some bodies are rarer than others, in virtue of a greater quantity of pores, or of vacuity lying between their parts or particles. The Cartesians hold, that a greater rarity only consists in a greater quantity of materia subtilis contained in the pores. And lastly, the Peripatetics contend, that rarity is a new quality superinduced on a body, without any dependence on either vacuity or subtile matter.

RAREFACTION, in Physics, the rendering a body rarer, that is bringing it to expand or occupy more room or space, without the accession of new matter: being thus opposed to condensation. The more accurate writers restrict the term rarefaction to that kind of expansion which is effected by means of heat: and the expansion from other causes they term Dilatation; if indeed there be other causes; for though some philosophers have attributed it to the action of a repulsive principle in the matter itself; yet from the many discoveries concerning the nature and properties of the electric fluid and fire, there is great reason to believe that this repulsive principle is no other than elementary fire.

The Cartesians deny any such thing as absolute rarefaction: extension, according to them, constituting the essence of matter, being obliged to hold all extension equally full. Hence they make rarefaction to be no other than an accession of fresh, subtile, and insensible matter, which, entering the parts of bodies, sensibly distends them.

It is by rarefaction that gunpowder has its effect; and to the same principle also we owe eolipiles, thermometers, &c. As to the air, the degree to which it is rarefiable exceeds all imagination, experience having shown it to be far above 10,000 times more than the usual state of the atmosphere; and as it is found to be above 1500 times denser in gunpowder than the atmosphere, it follows that experience has found it differ by about 15 millions of times. Perhaps indeed its degree of expansion is absolutely beyond all limits.

Such immense rarefaction, Newton observes, is inconceivable on any other principle than that of a repelling force inherent in the air, by which its particles mutually fly from one another. This repelling force, he observes, is much more considerable in air than in other bodies, as being generated from the most fixed bodies, and that with much difficulty, and scarcely without fermentation; those particles being always found to fly from each other with the greatest force, which, when in contact, cohere the most firmly together. See AIR.

On the rarefaction of the air is founded the useful method of measuring altitudes by the barometer, in all the cases of which, the rarity of the air is found to be inversely as the force that compresses it, or inversely as the weight of all the air above it at any place.

RARITY, thinness, subtlety; the contrary to density.

RATCH, or RASH, in Clock-Work, a kind of wheel having 12 fangs, which serve to lift up the detents every hour, to make the clock strike.

RATCHETS, in a Watch, are the small teeth at the bottom of the fusee, or barrel, that stop it in winding up.

RATIO, according to Euclid, is the habitude or relation of two magnitudes of the same kind in respect of quantity. So the ratio of 2 to 1 is double, that of 3 to 1 triple, &c. Several mathematicians have found fault with Euclid's definition of a ratio, and others have as much defended it, especially Dr. Barrow, in his Mathematical Lectures, with great skill and learning.

Ratio is sometimes confounded with proportion, but very improperly, as being quite different things; for proportion is the similitude or equality or identity of two ratios. So the ratio of 6 to 2 is the same as that of 3 to 1, and the ratio of 15 to 5 is that of 3 to 1 also; and therefore the ratio of 6 to 2 is similar or equal or the same with that of 15 to 5, which constitutes proportion, being thus expressed, 6 is to 2 as 15 to 5, or thus $6 : 2 :: 15 : 5$, which means the same thing. So that ratio exists between two terms, but proportion between two ratios or four terms.

The two quantities that are compared, are called the Terms of the ratio, as 6 and 2; the first of these 6 being called the Antecedent, and the latter 2 the Consequent. Also the Index or Exponent of the ratio, is the quotient of the two terms; so the index of the ratio of 6 to 2 is $\frac{6}{2}$ or 3, and which is therefore called a Triple ratio.

Wolfius divides ratios into Rational and Irrational.

Rational RATIO is that which can be expressed between two rational numbers; as the ratio of 6 to 2, or of $6\sqrt{3}$ to $2\sqrt{3}$, 3 to 1. And

Irrational RATIO is that which cannot be expressed by that of one rational number to another; as the ratio of $\sqrt{6}$ to $\sqrt{2}$, or of $\sqrt{3}$ to root $\sqrt{1}$, that is $\sqrt{3}$ to 1, which cannot be expressed in rational numbers.

When the two terms of a ratio are equal, the ratio is said to be that of Equality; as of 3 to 3, whose index is 1, denoting the single or equal ratio. But when the terms are not equal, as of 6 to 2, it is a Ratio of Inequality.

Further, when the antecedent is the greater term, as in 6 to 2, it is said to be the Ratio of Greater Inequality: but when the antecedent is the less term, as in the ratio of 2 to 6, it is said to be the Ratio of Less Inequality. In the former case, if the less term be an aliquot part of the greater, the ratio of greater inequality is said to be Multiplex or Multiple; and the ratio of the less inequality, Sub-multiple. Particularly, in the first case, if the exponent of the ratio be 2, as in 6 to 3, the ratio is called Duple or Double; if 3, as in 6 to 2, it is Triple; and so on. In the second case, if the ratio be $\frac{1}{2}$, as in 3 to 6, the ratio is called Subduple; if $\frac{1}{3}$, as in 2 to 6, it is Subtriple; and so on.

If the greater term contain the less once, and one aliquot part of the same over; the ratio of the greater inequality is called Superparticular, and the ratio of the less Subsuperparticular. Particularly, in the first case, if the exponent be $\frac{3}{2}$ or $1\frac{1}{2}$, it is called Sesquialterate; if $\frac{4}{3}$ or $1\frac{1}{3}$, Sesquitertial; &c. In the other case, if the exponent be $\frac{2}{3}$, the ratio is called Subsesquialterate; if $\frac{3}{4}$, it is subsesquitertial.

When the greater term contains the less once and several aliquot parts over, the ratio of the greater inequality is called Superpartiens, and that of the less inequality is Subsuperpartiens. Particularly, in the former case, if the exponent be $\frac{5}{3}$ or $1\frac{2}{3}$, the ratio is called Superbipartiens tertias; if the exponent be $\frac{7}{4}$ or $1\frac{3}{4}$, Supertripartiens quartas; if $\frac{11}{7}$ or $1\frac{4}{7}$, Superquadripartiens septimas; &c. In the latter case, if the exponent be the reciprocals of the former, or $\frac{3}{5}$, the ratio is called Subsuperbipartiens tertias; if $\frac{4}{7}$, Subsupertripartiens quartas; if $\frac{7}{11}$, Subsuperquadripartiens septimas; &c.

When the greater term contains the less several times, and some one part over; the ratio of the greater inequality is called Multiplex-superparticular; and the ratio of the less inequality is called Submultiplex subsuperparticular. Particularly, in the former case, if the exponent be $\frac{5}{2}$ or $2\frac{1}{2}$, the ratio is called Dupla sesquialtera; if $\frac{13}{4}$ or $3\frac{1}{4}$, Tripla sesquiquarta, &c. In the latter case, if the exponent be $\frac{2}{5}$, the ratio is called Subdupla subsesquialtera; if $\frac{4}{13}$, Subtripla subsesquiquarta, &c. Lastly, when the greater term contains the less several times, and several aliquot parts over; the ratio of the greater inequality is called Multiplex superpartiens; that of the less inequality, Submultiplex subsuperpartiens. Particularly, in the former case, if the exponent be $\frac{8}{3}$ or $2\frac{2}{3}$, the ratio is called Dupla superbipartiens tertias; if $\frac{25}{7}$ or $3\frac{4}{7}$, Tripla superbiquadripartiens septimas, &c. In the latter case, if the exponent be $\frac{3}{8}$, the ratio is called Subdupla subsuperbipartiens tertias; if $\frac{7}{25}$, Subtripla subsuperquadripartiens septimas; &c.

These are the various denominations of rational ratios, names which are very necessary to the reading of the ancient authors; though they occur but rarely among the modern writers, who use instead of them the smallest numeral terms of the ratios; such as 2 to 1 for duple, and 3 to 2 for sesquialterate, &c.

Compound RATIO, is that which is made up of two or more other ratios, viz, by multiplying the exponents together, and so producing the compound ratio of the product of all the antecedents to the product of all the consequents. Thus the compound ratio of 5 to 3,

and 7 to 4,

is the ratio of - - - - - - 35 to 12.

Particularly, if a ratio be compounded of two equal ratios, it is called the Duplicate ratio; if of three equal ratios, the Triplicate ratio; if of four equal ratios, the Quadruplicate ratio; and so on, according to the powers of the exponents, for all Multiplicate ratios. So the several multiplicate ratios of

the simple ratio of - - 3 to 2, are thus, viz,
the duplicate ratio - - 9 : 4,
the triplicate ratio - - 27 : 8,
the quadruplicate ratio 81 : 16, &c.

Properties of RATIOS. Some of the more remarkable properties of ratios are as follow:

1. The like multiples, or the like parts, of the terms of a ratio, have the same ratio as the terms themselves. So $a : b$, and $na : nb$, and $\frac{a}{n} : \frac{b}{n}$ are all the same ratio.

2. If to, or from, the terms of any ratio, be added or subtracted either their like parts, or their like multiples, the sums or remainders will still have the same ratio. So $a : b$, and $a \pm na : b \pm nb$, and $a \pm \frac{a}{n} : b \pm \frac{b}{n}$ are all the same ratio.

3. When there are several quantities in the same continued ratio, a, b, c, d, e, &c; whatever ratio the first has to the 2d,

the 1st to the 3d has the duplicate of that ratio,
the 1st to the 4th has the triplicate of that ratio,
the 1st to the 5th has the quadruplicate of it,

and so on. Thus, the terms of the continued ratio being $1, r, r^2, r^3, r^4, r^5$, &c, where each term has to the following one the ratio of 1 to r, the ratio of the 1st to the 2d; then $1 : r^2$ is the duplicate, $1 : r^3$ the triplicate, $1 : r^4$ the quadruplicate, and so on, according to the powers of $1 : r$.

For other properties see PROPORTION.

To approximate to a RATIO *in smaller Terms.*—Dr. Wallis, in a small tract at the end of Horrox's works, treats of the nature and solution of this problem, but in a very tedious way; and he has prosecuted the same to a great length in his Algebra, chap. 10 and 11, where he particularly applies it to the ratio of the diameter of a circle to its circumference. Mr. Huygens too has given a solution, with the reasons of it, in a much shorter and more natural way, in his Descrip. Autom. Planet. Opera Reliqua, vol. 1, pa. 174. The same has also Mr. Cotes, at the beginning of his Harmon. Mensurarum. And several other persons have done the same thing, by the same or similar methods.

The problem is very useful, for expressing a ratio in small numbers, that shall be near enough in practice, to any given ratio in large numbers, such as that of the diameter of a circle to its circumference. The principle of all these methods, consists in reducing the terms of the proposed ratio into a series of what are called continued fractions, by dividing the greater term by the less, and the less by the remainder, and so on, always the last divisor by the last remainder, after the manner of finding the greatest common measure of the two terms; then connecting all the quotients &c together in a series of continued fractions; and lastly collecting gradually these fractions together one after another. So if $\frac{b}{a}$ be any fraction, or the exponent of any ratio; then dividing thus,

```
a) b (c
   d) a (e
      f) d (g
         h) f (i
            k) h (l
               &c.
```

gives c, e, g, i, &c, for the several quotients, and these, formed in the usual way, give the approximate value of the given ratio in a series of continued fractions; thus,

$$\frac{b}{a} = c + \cfrac{1}{e + \cfrac{1}{g + \cfrac{1}{i + \&c.}}}$$

Then collecting the terms of this series, one after another, so many values of $\frac{b}{a}$ are obtained, always nearer and nearer; the first value being c or $\frac{c}{1}$, the next

$$c + \frac{1}{e} = \frac{ce+1}{e} = \frac{A}{B},$$

the 3d value $c + \cfrac{1}{e + \cfrac{1}{g}} = c + \cfrac{1}{\cfrac{ge+1}{g}} = c + \frac{g}{ge+1} =$

$$\frac{cge + c + g}{ge+1} = \frac{(ce+1)g + c}{ge+1} = \frac{Ag + c}{Bg + 1} = \frac{C}{D};$$ in like manner,

the 4th value is $\frac{Ci + A}{Di + B} = \frac{E}{F}$;

the 5th value is $\frac{El + C}{Fl + D} = \frac{G}{H}$; &c.

Hence comes this general rule: Having found any two of these values, multiply the terms of the latter of them by the next quotient, and to the two products add the corresponding terms of the former value, and the sums will be the terms of the next value, &c.

For example, let it be required to find a series of ratios in lesser numbers, constantly approaching to the ratio of 100000 to 314159, or nearly the ratio of the diameter of a circle to its circumference. Here first dividing, thus,

```
100000 ) 314159 ( 3 = c
     d = 14159 ) 100000 ( 7 = e
             f =   887 ) 14159 ( 15 = g
                     h =   854 ) 887 ( 1 = i, &c.
                                 &c,
```

there are obtained the quotients 3, 7, 15, 1, 25, 1, 7, 4. Hence 3 or $\frac{3}{1} = c$, the 1st value;

$$\frac{ce+1}{e} = \frac{3.7+1}{1.7} = \frac{22}{7} = \frac{A}{B},$$ the 2d value;

$$\frac{Ag+c}{Bg+1} = \frac{22.15+3}{7.15+1} = \frac{333}{106} = \frac{C}{D},$$ the 3d value;

$$\frac{Ci+A}{Di+B} = \frac{333.1+22}{106.1+7} = \frac{355}{113} = \frac{E}{F},$$ the 4th value; and so on; where the successive continual approximating values of the proposed ratio are $\frac{3}{1}$, $\frac{22}{7}$, $\frac{333}{106}$, $\frac{355}{113}$, &c; the 2d of these, viz, $\frac{22}{7}$, being the approximation of Archimedes; and the 4th, viz, $\frac{355}{113}$, is that of Metius, which is very near the truth, being equal to - - 3·1415929, the more accurate ratio being - - 3·1415927.

The Doctrine of Ratios and Proportions, as delivered by Euclid, in the fifth book of his Elements, is considered by most persons as very obscure and objectionable, particularly the definition of proportionality; and several ingenious men have endeavoured to elucidate that subject. Among these, the Rev. Dr. Abram Robertson, of Oxford, profes. of Astron. printed a neat little paper there in 1789, for the use of his classes, being a demonstration of that definition, in 7 propositions, the substance of which is as follows. He first premises this advertisement:

" As demonstrations depending upon proportionality pervade every branch of mathematical science, it is a matter of the highest importance to establish it upon clear and indisputable principles. Most mathematicians, both ancient and modern, have been of opinion that Euclid has fallen short of his usual perspicuity in this particular. Some have questioned the truth of the definition upon which he has founded it, and almost all who have admitted its truth and validity have objected to it, as a definition. The author of the following propositions ranks himself amongst objectors of the last-mentioned description. He thinks that Euclid must have founded the definition in question upon the reasoning contained in the first six demonstrations here given, or upon a similar train of thinking; and in his opinion a definition ought to be as simple, or as free from a multiplicity of conditions, as the subject will admit."

He then lays down these four definitions:

" 1. Ratio is the relation which one magnitude has to another, of the same kind, with respect to quantity."

" 2. If the first of four magnitudes be exactly as great when compared to the second, as the 3d is when compared to the fourth, the first is said to have to the second the same ratio that the third has to the fourth."

" 3. If the first of four magnitudes be greater, when compared to the second, than the third is when compared to the fourth, the first is said to have to the second a greater ratio than the third has to the fourth."

" 4. If the first of four magnitudes be less, when compared to the second, than the third is when compared to the fourth, the first is said to have to the second a less ratio than the third has to the fourth."

Dr. Robertson then delivers the propositions, which are the following:

" *Prop.* 1. If the first of four magnitudes have to the second, the same ratio which the third has to the fourth; then, if the first be equal to the second, the third is equal to the fourth; if greater, greater; if less, less."

" *Prop.* 2. If the first of four magnitudes be to the second as the third to the fourth, and if any equimultiples whatever of the first and third be taken, and also any equimultiples of the second and fourth; the multiple of the first will be to the multiple of the second as the multiple of the third to the multiple of the fourth."

" *Prop.* 3. If the first of four magnitudes be to the second as the third to the fourth, and if any like aliquot parts whatever be taken of the first and third, and any like aliquot parts whatever of the second and fourth, the part of the first will be to the part of the second as the part of the third to the part of the fourth."

" *Prop.* 4. If the first of four magnitudes be to the second as the third to the fourth, and if any equimultiples whatever be taken of the first and third, and any whatever of the second and fourth; if the multiple of the first be equal to the multiple of the second, the multiple of the third will be equal to the multiple of the fourth; if greater, greater; if less, less."

" *Prop.* 5. If the first of four magnitudes be to the second as the third is to a magnitude less than the fourth, then it is possible to take certain equimultiples of the first and third, and certain equimultiples of the second and fourth, such, that the multiple of the first shall be greater than the multiple of the second, but the multiple of the third not greater than the multiple of the fourth."

" *Prop.* 6. If the first of four magnitudes be to the second as the third is to a magnitude greater than the fourth, then certain equimultiples can be taken of the first and third, and certain equimultiples of the second and fourth, such, that the multiple of the first shall be less than the multiple of the second, but the multiple of the third not less than the multiple of the fourth."

" *Prop.* 7. If any equimultiples whatever be taken of the first and third of four magnitudes, and any equimultiples whatever of the second and fourth; and if when the multiple of the first is less than that of the second, the multiple of the third is also less than that of the fourth; or if when the multiple of the first is equal to that of the second, the multiple of the third is also equal to that of the fourth; or if when the multiple of the first is greater than that of the second, the multiple of the third is also greater than that of the fourth: then, the first of the four magnitudes shall be to the second as the third to the fourth."

And all these propositions Dr. Robertson demonstrates by strict mathematical reasoning.

RATIO, *Section of.* See SECTION *of a Ratio.*

RATIONAL, in Arithmetic &c, the quality of numbers, fractions, quantities, &c, when they can be expressed by common numbers; in contradistinction to irrational or surd ones, which cannot be expressed in common numbers. Suppose any quantity to be 1; there are infinite other quantities, some of which are commensurable to it, either simply, or in power: these Euclid calls Rational quantities. The rest, that are incommensurable to 1, he calls Irrational quantities, or Surds.

RATIONAL *Horizon*, or *True Horizon*, is that whose plane is conceived to pass through the centre of the earth; and which therefore divides the globe into two equal portions or hemispheres. It is called the rational horizon, because only conceived by the understanding; in opposition to the sensible or apparent horizon, or that which is visible to the eye.

RAVELIN, in Fortification, was anciently a flat bastion, placed in the middle of a curtain. But

RAVELIN, is now a detached work, composed only of two faces, which form a salient angle usually without flanks; being a triangular work resembling the point of a bastion with the flanks cut off. It is raised before the curtain, on the counterscarp of the place; and serving to cover it and the adjacent flanks from the direct fire of an enemy. It is also used to cover a bridge or a gate, and is always placed without the moat.—There are also double ravelins, which serve to defend each other; being so called when they are joined by a curtain.—What the engineers call a ravelin, the men usually call a demilune, or half-moon.

RAY, in Geometry, the same as RADIUS.

RAY, in Optics, a beam or line of light, propagated from a radiant point, through any medium. If the parts of a ray of light lie all in a straight line between the radiant point and the eye, the ray is said to be Direct: the laws and properties of which make the subject of Optics.—If any of them be turned out of that direction, or bent in their passage, the ray is said to be Refracted.—If it strike on the surface of any body, and be thrown off again, it is said to be Reflected.—In each case, the ray, as it falls either directly on the eye, or on the point of reflection, or of refraction, is said to be Incident.

Again, if several rays be propagated from the radiant object equidistantly from one another, they are called Parallel rays. If they come inclining towards each other, they are called Converging rays. And if they go continually receding from each other, they are called Diverging rays.

It is from the different circumstances of rays, that the several kinds of bodies are distinguished in optics. A body, for example, that diffuses its own light, or emits rays of its own, is called a Radiating or Lucid or Luminous body. If it only reflect rays which it receives from another, it is called an Illuminated body. If it only transmit rays, it is called a Transparent or Translucent body. If it intercept the rays, or refuse them passage, it is called an Opaque body.

It is by means of rays reflected from the several points of illuminated objects to the eye, that these become visible, and that vision is performed; whence such Rays are called Visual rays.

The rays of light are not homogeneous, or similar, but differ in all the properties we know of; viz, refrangibility, reflexibility, and colour, and even heat. It is probably from the different refrangibility that the other differences have their rise; at least it appears that those rays which agree or differ in this, do so in all the rest. It is not however to be understood that the property or effect called colour, exists in the rays of light themselves; but from the different sensations the differently disposed rays excite in us, we call them Red rays, Yellow rays, &c. Each beam of light however, as it comes from the sun, seems to be compounded of all the kinds of rays mixed together; and it is only by splitting or separating the parts of it, that these different sorts become observable; and this is done by transmitting the beam through a glass prism, which refracting it in the passage, and the parts that excite the different colours having different degrees of refrangibility, they are thus separated from one another, and exhibited each apart, and appearing of the different colours.

Besides refrangibility, and the other properties of the rays of light already ascertained by observation and experiment, sir I. Newton suspects they may have many more; particularly a power of being inflected or bent by the action of distant bodies; and those rays which differ in refrangibility, he conceives likewise to differ in flexibility.

These rays he suspects may be very small bodies emitted from shining substances. Such bodies may have all the conditions of light: and there is that action and reaction between transparent bodies and light, which very much resembles the attractive force between other bodies. Nothing more is required for the production of all the various colours, and all the degrees of refrangibility, but that the rays of light be bodies of different sizes; the least of which may make violet the weakest and darkest of the colours, and be the most easily diverted by refracting surfaces from its rectilinear course; and the rest, as they are larger and larger, may make the stronger and more lucid colours, blue, green, yellow, and red. See COLOUR, LIGHT, REFRACTION, REFLECTION, INFLECTION, CONVERGING, DIVERGING, &c, &c.

Among other qualities of rays, it has been found by experiment, that there is a great difference in the heating power of solar rays. From Dr. Herschel's experiments it appears, that this heating power increases from the middle of the spectrum to the red ray, and is greatest beyond it, where the rays are invisible. Hence it is inferred that the rays of light and caloric nearly accompany each other, and the latter are in different proportions in the different coloured rays. They are easily separated from each other; as when the sun's rays are transmitted through a transparent body, the rays of light pass on seemingly undiminished, but the rays of caloric are intercepted. When the sun's rays are directed to an opaque body, the rays of light are reflected, but the rays of caloric are absorbed and retained. This is the case with the moon's light, which, however much it be concentrated, is not accompanied with heat. It has also been shown, that the different rays of light produce different chemical effects on the metallic salts and oxyds. These effects increase on the opposite direction of the spectrum, from the heating power of the rays. From the middle of the spectrum, towards the violet end, they become more powerful, and produce the greatest effect beyond the visible rays. From these discoveries it appears that the solar rays are of three kinds: 1. Rays which produce heat; 2. Rays which produce colour; and 3. Rays which deprive metallic substances of their oxygen. The first set of rays is in the greatest abundance, or are most powerful towards the red end of the spectrum, and are least refracted. The 2d set, or those which illuminate objects, are most powerful in the middle of the spectrum. And the 3d set produce the greatest effect towards the violet end, where the rays are most refracted. The solar rays pass through transparent bodies, without heating them. The atmosphere, for instance, receives no increase of heat by transmitting the sun's rays, till these rays are reflected from other bodies, or are communicated to it by bodies which have absorbed them. This is also proved by the sun's rays being transmitted through convex lenses, producing a high degree of temperature when they are concentrated, but giving no increase of heat to the glass itself. By this method the heat which proceeds from the sun can be greatly increased. Indeed, the intensity of heat produced in this way is equal to that of the hottest furnace. This is done, either by reflecting the sun's rays from a concave polished mirror, or by concentrating or collecting them, by the refractive power of convex lenses, and directing the rays, thus concentrated, on the combustible body.

Reflected RAYS, those rays of light which are reflected, or thrown back again, from the surfaces of bodies upon which they strike. It is found that, in all the rays of light, the angle of reflection is equal to the angle of incidence.

Refracted RAYS, are those rays of light, which are bent or broken, in passing out of one medium into another.

Pencil of RAYS, a number of rays emitted from a point of an object, and diverging in the form of a cone.

Principal RAY, in Perspective, is the perpendicular distance between the eye and the vertical plane or table, as it is sometimes named.

RAY *of Curvature*. See *Radius of* CURVATURE.

REAUMUR (RENE-ANTOINE-FERCHAULT, Sieur de), a respectable French philosopher, was born at Rochelle in 1683. After the usual course of school education, he was sent to Poitiers to study philosophy, and, in 1699, to Bourges to study the law, the profession for which he was intended. But philosophy and mathematics having very early been his favourite pursuits, he quitted the law, and repaired to Paris in 1703, to pursue those sciences to the best advantage; and here his character procured him a seat in the academy in the year 1708; which he held till the time of his death, which happened the 18th of November 1757, at 74 years of age.

Reaumur soon justified the choice that was made of him by the academy. He made innumerable observations, and wrote a great number of pieces on the various branches of natural philosophy. His History of Insects, in 6 vols. quarto, at Paris, is his principal work. Another edition was printed in Holland, in 12 vols. 12mo. He made also great and useful discoveries concerning iron; showing how to change common wrought iron into steel, how to soften cast iron, and to make works in cast iron as fine as in wrought iron. His labours and discoveries on this subject were rewarded by the duke of Orleans, regent of the kingdom, by a pension of 12 thousand livres, equal to about 500l. sterling; which however he would not accept but on condition of its being put under the name of the academy, who might enjoy it after his death. It was owing to Reaumur's endeavours that there were established in France manufactures of tin-plates, of porcelain in imitation of china-ware, &c. They owe to him also a new thermometer, which bears his name, and is pretty generally used on the continent, while that of Fahrenheit is used in England, and some few other places. Reaumur's thermometer is a spirit one, having the freezing point at 0, and the boiling point at 80.

Reaumur is esteemed an exact and clear writer; and there is an elegance in his style and manner, which is not commonly found among those who have made only the sciences their study. He is represented also as a man of a most amiable disposition, and with qualities to make him beloved as well as admired. He left a great variety of papers and natural curiosities, which he bequeathed to the Academy of Sciences.—The works published by him, are the following:

1. The Art of changing Forged Iron into Steel; of Softening Cast Iron; and of making works of Cast Iron, as fine as of Wrought Iron. Paris, 1722, 1 vol. in 4to.

2. Natural History of Insects, 6 vols. in 4to.

His memoirs printed in the volumes of the Academy of Sciences, are very numerous, amounting to upwards of a hundred, and on various subjects, from the year 1708 to 1763, several papers in almost every volume.

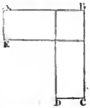
RECEIVER, of an Air Pump, is part of its apparatus; being a glass vessel placed on the top of the plate, out of which the air is to be exhausted.

RECESSION *of the Equinoxes*. See PRECESSION.

RECIPROCAL, in Arithmetic, &c, is the quotient arising by dividing 1 by any number or quantity. So, the reciprocal of 2 is $\frac{1}{2}$; of 3 is $\frac{1}{3}$, and of a is $\frac{1}{a}$, &c. Hence, the reciprocal of a vulgar fraction is found, by barely making the numerator and the denominator mutually change places: so the reciprocal of $\frac{1}{2}$ is $\frac{2}{1}$ or 2; of $\frac{2}{3}$, is $\frac{3}{2}$; of $\frac{a}{b}$, is $\frac{b}{a}$, &c. Hence also, any quantity being multiplied by its reciprocal, the product is always equal to unity or 1: so $\frac{1}{2} \times \frac{2}{1} = \frac{2}{2} = 1$, and $\frac{2}{3} \times \frac{3}{2} = \frac{6}{6} = 1$, and $\frac{a}{b} \times \frac{b}{a} = \frac{ab}{ab} = 1$.

See a large table of reciprocals of numbers, in my Tracts, vol. 1, at the end, also a method of finding them, pa 463.

RECIPROCAL *Figures*, in Geometry, are such as have the antecedents and consequents of the same ratio in both figures. So, in the two rectangles BE and BD, if AB : DC :: BC : AE, then those rectangles are reciprocal figures; and are also equal.



RECIPROCAL *Proportion*, is when, in four quantities, the two latter terms have the reciprocal ratio of the two former, or are proportional to the reciprocals of them. Thus, 24, 15, 5, 8 form a reciprocal proportion, because $\frac{1}{24} : \frac{1}{15} :: 5 : 8$, or $15 : 24 :: 5 : 8$.

RECIPROCAL *Ratio*, of any quantity, is the ratio of the reciprocal of the quantity.

RECIPROCALLY. One quantity is reciprocally as another, when the one is greater in proportion as the other is less; or when the one is proportional to the reciprocal of the other. So a is reciprocally as b, when a is always proportional to $\frac{1}{b}$. Like as in the mechanic powers, to perform any effect, the less the power is, the greater must be the time of performing it: or, as it is said, what is gained in power, is lost in time. So that, if p denote any power or agent, and t the time of its performing any given service; then p is as $\frac{1}{t}$, and t is as $\frac{1}{p}$; that is, p and t are reciprocally proportionals to each other.

RECIPROCITY of prime numbers, a certain law that obtains with regard to the remainders of the formulæ $\frac{m^{\frac{n-1}{2}}}{n}$ and $\frac{n^{\frac{m-1}{2}}}{m}$, when n and m are both primes, first demonstrated by Legendre, and on which he has founded the demonstration of several curious numerical propositions. These remainders, for the sake of abridgement, may be written $(\frac{m}{n})$ and $(\frac{n}{m})$; that is, $(\frac{m}{n})$ representing the remainders of $\frac{m^{\frac{n-1}{2}}}{n}$, and $(\frac{n}{m})$ representing the remainders of $\frac{n^{\frac{m-1}{2}}}{m}$. Then there always subsists such a relation between these two expressions, that one being given, the other is immediately determined. For whatever may be the form of m and n, provided they are not both of the form $4a-1$, we shall always have $(\frac{n}{m}) = (\frac{m}{n})$; and if they are both of the form $4a-1$, then will $(\frac{n}{m}) = -(\frac{m}{n})$. It is not expected we should here enter upon the investigation of this theorem, but the reader who wishes to see the demonstration, will find ample gratification by consulting the work above alluded to.

RECKONING, in Navigation, is the estimating the quantity of a ship's way; or of the course and distance run. Or, more generally, a ship's reckoning is that account, by which it may at any time be known where the ship is, and consequently on what course or courses she must steer to gain her intended port. The reckoning is usually performed by keeping an account of the courses steered, and the distance run, with any accidental circumstances that occur. The courses steered are observed by the compass; and the distances run are estimated from the rate of running, and the time run upon each course. The rate of running is measured by the log, from time to time; which however is liable to great irregularities. Anciently Vitruvius, for measuring the rate of sailing, advised an axis to be passed through the sides of the ship, with two large heads protending out of of the ship, including wheels touching the water, by the revolution of which the space passed over in a given time is measured. And the same has been since recommended by Snell.

RECKONING, *Dead*. See DEAD *Reckoning*.

RECLINATION *of a Plane*, in Dialling, is the angular quantity which a dial plane leans backwards, from an exactly upright or vertical plane, or from the zenith.

RECLINER, or RECLINING *Dial*, is a dial whose plane reclines from the perpendicular, that is, leans backwards, or from you, when you stand before it.

RECLINER, *Declining*, or *Declining* RECLINING *Dial*, is one which neither stands perpendicularly, nor opposite to one of the cardinal points.

RECOIL, or REBOUND, the resilition, or flying backward, of a body, especially a fire-arm. This is the motion by which, on explosion, it starts or flies backwards; and the cause of it is the resistance of the ball and the impelling force of the powder, which acts equally on the gun and on the ball. It has been commonly said by authors, that the momentum of the ball is equal to that of the gun with its carriage together; but this is a mistake; for the latter momentum is nearly equal to that of the ball and half the weight of the powder together, moving with the velocity of the ball. So that, if the gun, and the ball with half the powder, were of equal weight, the piece would recoil with the same velocity as the ball is discharged. But the heavier any body is, the less will its velocity be, to have the same momentum, or force; and therefore so many times as the cannon and carriage is heavier than the ball and half the powder, just as many times will the velocity of the ball be greater than that of the gun; and in the same ratio nearly is the length of the barrel before the charge, to the quantity the gun recoils in the time the ball is passing along the bore of the gun. So, if a 24 pounder of 10 feet long be 6400lb weight, and charged with 8lb of powder; then, when the ball quits the piece, the gun will have recoiled $\frac{28}{6400} \times 10 = \frac{7}{160}$ of a foot, or nearly half an inch.

RECORDE (Robert), a learned physician and mathematician, was born of a good family in Wales, and flourished in the reigns of Henry the 8th, Edward the 6th, and Mary. There is no account of the exact time of his birth, though it must have been early in the 16th century, as he was entered of the university of Oxford about the year 1525, where he was elected fellow of All-souls college in 1531. Making physic his profession, he went to Cambridge, where he was honoured with the degree of doctor in that faculty, in 1545, and was highly esteemed by all who knew him, for his great knowledge in several arts and sciences. He afterwards returned to Oxford, where, as he had done before he went to Cambridge, he publicly taught arithmetic, and other branches of the mathematics, with great applause. It seems he afterwards repaired to London, and it has been said he was physician to Edward the 6th and Mary, to which princes he dedicates some of his books; and yet he ended his days in the Fleet, where he was confined for debt, in the year 1558, at a very immature age. See other curious particulars of this author in my Tracts, vol. 2, pa. 243.

Recorde published several mathematical books, which are mostly in dialogue, between the master and scholar. They are as follow:

1. *The Pathway to Knowledge*, containing the first Principles of Geometrie, as they may moste aptly be applied unto practise, bothe for use of Instrumentes Geometricall and Astronomicall, and also for Projection of Plattes much necessary for all sortes of men. Lond. 4to, 1551.—This work, the author says, is the first book on Geometry ever printed in the English language.

2. *The Ground of Arts*, teaching the perfect worke and practice of Arithmeticke, both in whole numbers and fractions, after a more easie and exact forme then in former time hath beene set forth, 8vo. 1552.—It would seem however that there must have been some earlier edition than this, or another like work, since the author, in the dedication of his Geometry, or Pathway, Jan. 1551, says that he has "allready set forth somwhat of Arithmetike."—This work went through many editions, and was corrected and augmented by several other persons; as first by the famous Dr. John Dee; then by John Mellis, a schoolmaster, 1590; next by Robert Norton; then by Robert Hartwell, practitioner in mathematics, in London; and lastly by R. C. and printed in 8vo, 1623.

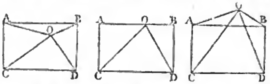
3. *The Castle of Knowledge*, containing the Explication of the Sphere bothe Celestiall and Materiall, and divers other things incident thereto. With sundry pleasaunt proofes and certaine newe demonstrations not written before in any vulgare woorkes. Lond. folio, 1556.

4. *The Whetstone of Witte*, which is the seconde part of Arithmetike: containing the Extraction of Rootes: the Cossike Practise, with the rules of Equation: and the woorkes of Surde Nombers. Lond. 4to, 1557.—For an analysis of this work on Algebra, with an account of what is new in it, see vol. 1, under the article Algebra.

Wood says he wrote also several pieces on physic, anatomy, politics, and divinity; but I know not whether they were ever published. And Sherburne says that he published Cosmographiæ Isagogen; also that he wrote a book, De Arte faciendi Horologium; and another, De Usu Globorum, & de Statu Temporum; which I have never seen.—In the end of the preface to the Geometrical Theorems, in The Pathway to Knowledge, he sets down a list of many other books, partly mathematical and partly other subjects, which he says he had written, but not then published.

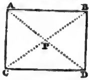
RECTANGLE, in Geometry, is a right-angled parallelogram, or a right-angled quadrilateral figure.

If from any point O, lines be drawn to all the four



angles of a rectangle; then the sums of the squares of the lines drawn to the opposite corners will be equal, in whatever part of the plane the point O is situated; viz, $OA^2 + OD^2 = OB^2 + OC^2$. For other properties of the rectangle, see Parallelogram; for the rectangle being a species of the parallelogram, whatever properties belong to the latter, must equally hold in the former.

For the Area of a Rectangle. Multiply the length by the breadth or height. *Otherwise;* Multiply the product of the two diagonals by half the sine of their angle at the intersection.



That is, $AB \times AC$, or $AD \times BC \times \frac{1}{2}\sin\angle P =$ area. A rectangle, as of two lines AB and AC, is thus denoted, $AB \times AC$, or $AB . AC$; or else thus expressed, the rectangle of, or under, AB and AC.

Rectangle, in Arithmetic, is the same with product or factum. So the rectangle of 3 and 4, is 3×4 or 12; and of a and b is $a \times b$ or ab.

RECTANGLED, Right-angled, or Rectangular, is applied to figures and solids that have at least one right angle, if not more. So a right-angled triangle has one right angle: a right-angled parallelogram is a rectangle, and has four right angles. Such also are squares, cubes, and parallelopipedons. Solids are also said to be rectangular with respect to their situation, viz, when their axis is perpendicular to their base; as right cones, pyramids, cylinders, &c.

The ancients used the phrase Rectangular Section of a Cone, to denote a parabola; that conic section, before Apollonius, being only considered in a cone having its vertex a right angle. And hence it was, that Archimedes entitled his book of the quadrature of the parabola, by the name of Rectanguli Coni Sectio.

RECTIFICATION, in Geometry, is the finding of a right line equal to a curve. The rectification of curves is a branch of the higher geometry, in which the use of the inverse method of fluxions is particularly useful. This is a problem to which all mathematicians, both ancient and modern, have paid the greatest attention, and particularly as to the rectification of the circle, or finding the length of the circumference, or a right line equal to it; but hitherto without the perfect effect: on this also depends the quadrature of the circle, since it is demonstrated that the area of a circle is equal to a right-angled triangle, of which one of the sides about the right angle is the radius, and the other equal to the circumference: but it is much to be feared that neither the one nor the other will ever be accomplished. Innumerable approximations however have been made, from Archimedes, down to the mathematicians of the present day. See CIRCLE, and CIRCUMFERENCE.

The first person who gave the rectification of any curve, was Mr. Neal, son of Sir Paul Neal, as we find at the end of Dr. Wallis's Treatise on the Cissoid; where he says, that Mr. Neal's rectification of the curve of the semicubical parabola, was published in July or August, 1657. Two years after, viz, in 1659, Van Hureat, in Holland, also gave the rectification of the same curve; as may be seen in Schooten's Commentary on Descartes's Geometry.

The most comprehensive method of rectification of curves, is by the inverse method of fluxions, which is thus: Let ACc be any curve line, AB an abscisa, and BC

a perpendicular ordinate; also bc another ordinate indefinitely near to BC; and cd drawn parallel to the abscisa AB. Put the abscisa AB $= x$, the ordinate BC $= y$, and the curve AC $= z$: then is $cd = Bb = \dot{x}$ the fluxion of the abscisa AB, and $cd = \dot{y}$ the fluxion of the ordinate BC, also $Cc = \dot{z}$ the fluxion of the curve AB. Hence, because Ccd may be considered as a plane right-angled triangle, $Cc^2 = Cd^2 + cd^2$, or $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$; and therefore $\dot{z} = \sqrt{(\dot{x}^2 + \dot{y}^2)}$; which is the fluxion of the length of any curve; and consequently, out of this equation expelling either $\dot{x}$ or $\dot{y}$, by means of the particular equation expressing the nature of the curve in question, the fluents of the resulting equation, being then taken, will give the length of the curve, in finite terms when it is rectifiable, otherwise in an infinite series, or in a logarithmic or exponential &c expression, or by means of some other curve, &c.

Ex. 1. *To rectify the common parabola.*—In this case, the equation of the curve is $2ax = y^2$, where a is half the parameter. The fluxion of this equation is $a\dot{x} = y\dot{y}$, and hence $\dot{x}^2 = \frac{y^2\dot{y}^2}{a^2}$; this being substituted in the general equation $\dot{z} = \sqrt{(\dot{x}^2 + \dot{y}^2)}$, it becomes $\dot{z} = \frac{\dot{y}\sqrt{(aa + yy)}}{a}$; the correct fluents of which give $z = \frac{y\sqrt{(aa + yy)}}{2a} + \frac{1}{2}a \times$ hyp. log. of $\frac{y + \sqrt{(aa + yy)}}{a}$, which is the length of the curve AC, when it is a parabola.

And the same might be expressed by an infinite series, by expanding the quantity $\sqrt{(aa + yy)}$. See my Mensuration, pa. 271, 4th edition.

Ex. 2. *To rectify the Circle.*—The equation of the circle may be expressed either in terms of the sine, or versed sine, or tangent, or secant, &c, and the radius. Let therefore the radius of the circle be DA or DC $= r$, the versed sine AB $= x$, the right sine BC $= y$, the tangent CE $= t$, and the secant DE $= s$; then, by the nature of the circle, we have these equations, $y^2 = 2rx - x^2 = \frac{r^2t^2}{r^2 + t^2} = \frac{s^2 - r^2}{s^2}r^2$; and by means of the fluxions of these equations, with the general equation $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$, are obtained the following fluxional forms for the fluxion of the curve, the fluent of any one of which will be the curve itself, viz,

$$\dot{z} = \frac{r\dot{x}}{\sqrt{(2rx - xx)}} = \frac{r\dot{y}}{\sqrt{(r^2 - y^2)}} = \frac{r^2\dot{t}}{r^2 + t^2} = \frac{r^2\dot{s}}{\sqrt{(s^2 - r^2)}}.$$

Hence the value of the curve, from the fluent of each of these, gives the four following forms, in series, viz, putting $d = 2r$ the diameter, the curve is, z

$$= (1 + \frac{x}{2 \cdot 3d} + \frac{3x^2}{2 \cdot 4 \cdot 5d^2} + \frac{3 \cdot 5x^3}{2 \cdot 4 \cdot 6 \cdot 7d^3} \&c)\sqrt{dx},$$

$$= (1 + \frac{y^2}{2 \cdot 3r^2} + \frac{3y^4}{2 \cdot 4 \cdot 5r^4} + \frac{3 \cdot 5y^6}{2 \cdot 4 \cdot 6 \cdot 7r^6} \&c)y,$$

$$= (1 - \frac{t^2}{3r^2} + \frac{t^4}{5r^4} - \frac{t^6}{7r^6} + \frac{t^8}{9r^8} - \&c)t,$$

$$= (\frac{s - r}{s} + \frac{s^3 - r^3}{2 \cdot 3s^3} + \frac{3(s^5 - r^5)}{2 \cdot 4 \cdot 5s^5} + \&c)r.$$

See my Mensur. 4th edit. pa. 91 &c, also most treatises on Fluxions.

It is evident that the simplest of these series is the third, or that which is expressed in terms of the tangent. It will therefore be the properest form to calculate an example by in numbers. And for this purpose it will be convenient to assume some arc whose tangent, or at least its square, is known to be some small simple number. Now the arc of 45° it is known has its tangent equal to the radius; and therefore, taking the radius $r = 1$, and consequently the tangent of 45° or $t = 1$ also, in this case the arc of 45° to the radius 1, or the quadrant to the diameter 1, will be $= 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c. But as this series converges very slowly, some smaller arch must be taken, that the series may converge faster; such as the arc of 30°, whose tangent is $= \sqrt{\frac{1}{3}} = \cdot5773502$, or its square $t^2 = \frac{1}{3}$; and hence, after the first term, the succeeding terms will be found by dividing always by 3, and these quotients divided by the absolute numbers 3, 5, 7, 9, &c; and lastly adding every other term together into two sums, the one the sum of the positive terms, and the other the sum of the negative ones, then lastly the one sum taken from the other leaves the length of the arc of 30°, which is the 12th part of the whole circumference when the radius is 1, or the 6th part when the diameter is 1, and consequently 6 times that arc will be the length of the whole circumference to the diameter 1; therefore multiply the 1st term $\sqrt{\frac{1}{3}}$ by 6, and the product is $\sqrt{\frac{36}{3}}$ or $\sqrt{12} = 3\cdot4641016$; hence the operation will be conveniently made as follows:

		+ Terms.	− Terms.
1)	3.4641016	(3·4641016	
3)	1·1547005	(	0·3849002

19)	1760	(	93
21)	587	(28	
23)	196	(	8
25)	65	(3	
27)	22	(	1
		+ 3·5462332	− 0·4046406
		− 0·4046406	
		3·1415926 the circumference.	

Various other series for the rectification of the circle may be seen in different parts of my Mensuration. See also my Tracts, vol. 1, Tr. 17 and 18.

RECTIFIER, in Navigation, is an instrument used for determining the variation of the compass, in order to rectify the ship's course. It consists of two circles, either laid upon, or let in to one another, and so fastened together in their centres that they represent two compasses, the one fixed, and the other moveable. Each is divided into 32 points of the compass, and 360°, and numbered both ways, from the north and the south, ending at the east and west in 90°. The fixed compass represents the horizon, in which the north, and all the other points, are liable to variation. In the centre of the moveable compass is fastened a silk thread, long enough to reach the outside of the fixed compass, except when the instrument is made of wood, in which case an index is used instead of the thread.

RECTIFYING *of Curves*. See RECTIFICATION.

RECTIFYING *of the Globe or Sphere*, is a previous adjustment of it, to prepare it for the solution of problems. This usually consists in placing it in the same position as the true sphere of the world has at some certain time proposed: which is done first by elevating the pole above the horizon as much as the latitude of the place is, then bringing the sun's place for the given day, found in the ecliptic, to the graduated side of the brass or general meridian, next move the hour-index to the upper hour of 12, so shall the globe be rectified for noon of that day; and if the globe be turned about till the hour-index point at any proposed hour, then is the globe in the real position of the earth at that time, if the whole globe be set in the north and south position by means of the compass.

RECTILINEAL, RECTILINEAR, or *Right-lined*, is the quality or nature of figures that are bounded by right lines, or formed by right lines.

RECURRING *Series*, is a series constituted in such a manner, that having taken at pleasure any number of its terms, each following term shall be related to the same number of preceding terms according to a constant law of relation. See *Recurring* SERIES.

RECURRING *Decimals*. See REPETEND.

RED, in Physics, or Optics, one of the simple or primary colours of natural bodies, or rather of the rays of light.—The red rays are the least refrangible of all the rays of light. And hence, as Newton supposes the different degrees of refrangibility to arise from the different magnitudes of the luminous particles of which the rays consist; therefore the red rays, or red light, is concluded to be that which consists of the largest particles. See COLOUR, and LIGHT.—Authors distinguish three general kinds of red: one bordering on the blue, as colombine, or dove-colour, purple, and crimson; another bordering on yellow, as flame-colour and orange; and between these extremes is a medium, which is that which is properly called red.

REDANS, or REDANT, or REDENT, in Fortification, is a kind of work indented like the teeth of a saw, with salient and re-entering angles; to the end that one part may flank or defend another. It is called also Saw-work, and Indented work.—Redans are often used in fortifying of walls, where it is not necessary to be at the expense of building bastions; as when they stand on the side of a river, or a marsh, or the sea, &c. But the fault of such fortification is, that the besiegers from one battery may ruin both sides of the tenaille or front of a place, and make an assault without fear of being enfiladed, since the defences are ruined.—The parapet of the corridor also is frequently redented, or carried on by the way of redans.

REDOUBT, or REDOUTE, in Fortification, a small fort, without any defence but in front, used in trenches, lines of circumvallation, contravallation, and approach, as also for the lodging of corps de garde, and to defend passages.

A Detached REDOUBT, is a kind of work resembling a ravelin, with flanks, placed beyond the glacis.—It is made to occupy some spot of ground which might be advantageous to the besiegers; and also to oblige the enemy to open his trenches farther off than he would otherwise do.

REDUCING *Scale*, or SURVEYING *Scale*, is a broad thin slip of box, or ivory, having several lines and scales of equal parts upon it; used by surveyors for turning chains and links into roods and acres, by inspection. They use it also to reduce maps and draughts from one dimension to another.

REDUCTION, in general, is the bringing or changing some thing to a different form, state, or denomination.

REDUCTION, in *Arithmetic*, is commonly understood of the changing of money, weights, or measures, to other denominations, of the same value; and it is of two kinds, Reduction Descending, which is the changing a number to its equivalent value in a lower denomination; as pounds into shillings or pence: and Reduction Ascending, which is the changing numbers to higher denominations; as pence to shillings or pounds. See the books on arithmetic.

REDUCTION *of Fractions*. See FRACTION, and DECIMAL.

REDUCTION *of Equations*. See EQUATION.

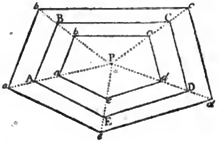
REDUCTION *of Curves*. See CURVE.

REDUCTION *of a Figure, Design, or Draught*, is the making a copy of it, either larger or smaller than the original, but still preserving the form and proportion.

Figures and plans are reduced, and copied, in various ways; as by the pentagraph, and proportional compasses. See PENTAGRAPH, and *Proportional* COMPASSES. The best of the other methods of reducing are as below.

To reduce a simple Rectilinear Figure by Lines.

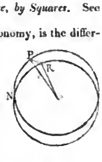
Choose a point P any where about the given figure ABCDE, either within it, or without it, or in one side or angle; but near the middle is best. From that point P draw lines through all the angles; on one of which take PA to PA in the proposed proportion of the scales, or linear dimensions; then draw *ab* parallel to AB, *bc* to BC, &c; so shall *abcde* be the reduced figure sought, either greater or smaller than the original.



To Reduce a Figure by a Scale.—Measure all the sides, and diagonals, of the figure, as ABCDE, by a scale; and lay down the same measures respectively, from another scale, in the proportion required.

To Reduce a Map, Design, or Figure, by Squares. See SURVEYING, art. 21.

REDUCTION *to the Ecliptic*, in Astronomy, is the difference between the argument of latitude, as NP, and an arc of the ecliptic NR, intercepted between the place of a planet, and the node.—To find this reduction, or difference; in the right-angled spherical triangle NPR, are given the angle of inclination, and the argument of latitude NP; to find NR; then the dif. between NP and NR is the reduction sought.



REDUNDANT *Hyperbola*, is a curve of the higher kind, so called because it exceeds the conical hyperbola in the number of legs; being a triple hyperbola, with 6 hyperbolic legs. See Newton's Enum. Lin. tertii Ordinis, nomina formarum, &c.

RE-ENTERING *Angle*, in Fortification, is an angle whose point is turned inwards, or towards the place.

REFLECTED *Ray*, or *Vision*, is that which is made by the reflection of light, or by light first received upon the surface of some body, and thence reflected again. See RAY, VISION, and REFLECTION.

REFLECTING *Circle*, or *Semicircle*, an ingenious and useful instrument, adapted to the purposes of surveys, especially those of the military kind, in forming sketches in the practice of reconnoitering.

This instrument is the invention of sir Howard Douglas Bart. lieutenant-governor of the senior department of the Royal Military College, at Farnham; and which, with the many useful regulations and good management of the college, are so many verifications of the promising hopes indicated by his talents and regular good conduct in the Royal Mil. Acad. at Woolwich, where sir Howard received his military education.

The instrument combines the effect of a Hadley's quadrant and of a protractor, together; or it combines the measuring principle with a circular protractor, in such a manner, that the index or limb of the instrument shall describe the *whole* of the measured angle. By this contrivance, the angles taken in the field, may be protracted at once, in their real magnitude, on the sketch, without the trouble of reading off the degrees. It is therefore particularly useful in surveying, to determine the true situations of objects, at the same time that the ground is sketched.

To the radius or limb of a semicircular, or circular, protractor, ABC (pl. 31, fig. 2), is fixed the index glass DE; and the horizon glass FG is fixed on a bar, HI, which has a motion on the centre K. This bar slides on a pin O, attached to the limb or radius carrying the index glass; the pin being adjusted so, that there shall be no apparent index-error, and exactly in the same circle with the point K: the principal limb will then describe the whole angle measured.

Thus the new reflecting circle, or semicircle, is divided into 360°, 180°, instead of the double number, as in the repeating circle, and the length of the arc of the latter is equal to that of a sextant, whose radius is the length of the sliding bar, that is, the diameter of the circle. A vernier is applied to read off with accuracy. A 4-inch plotting or diagonal scale of 1 mile, divided into yards, is engraven on the fixed limb of the instrument; by help of which all the cases of trigonometry can be solved by construction.

To those acquainted with the common sextant, the use of the reflecting semicircle will be obvious. The eye is applied to the end of the bar Q: the instrument is held in the right hand, by the end of the fixed limb, and is directed so that the left, or direct object, is seen through the unsilvered part of the horizon glass. Apply the thumb of the left hand to the end of the moveable limb, and turn it till the other object is seen reflected in the lower part of the horizon glass; then PRS is the measured angle, which can be protracted at once, placing the centre R over the station.—The errors or mistakes arising from reading off in a hurry, are thus avoided; the operations of protracting the points, and sketching the features of the ground, are combined; and the sketch much sooner completed.

M is a small screw, to adjust the horizon glass perpendicular to the plane of the instrument; and N is another small screw, behind the index glass, to adjust it parallel to the horizon glass, when the vernier cuts 0 degree on the arc.

For other instruments of reflection, see CIRCULAR *Instrument*.

REFLECTING, or REFLEXIVE, *Dial*, is a kind of dial which shows the hour by means of a thin piece of looking-glass plate, duly placed to throw the sun's rays to the top of a cieling, on which the hour-lines are drawn.

REFLECTING *Telescope*, is one in which the rays, from the object to be viewed, are first received on a speculum, or polished reflecting surface, of a proper form, thence to another speculum, and so to the eye. See TELESCOPE.

REFLECTION, or REFLEXION, in Mechanics, is the return, or regressive motion of a moveable body, occasioned by the resistance of another body, which hinders it from pursuing its former course of direction.

Reflection is conceived, by the latest and best authors, as a motion peculiar to elastic bodies, by which, after striking on others which they cannot remove, they recede, or turn back, or aside, by their elastic power. On this principle it is asserted, that there may be, and is, a period of rest between the incidence and the reflection; since the reflected motion is not a continuation of the other, but a new motion, arising from a new cause or principle, viz, the power of elasticity.

It is one of the great laws of reflection, that the angle of incidence is equal to the angle of reflection; i. e. that the angle which the direction of motion of a striking body makes with the surface of the body struck, is equal to the angle made between the same surface and the direction of motion after the stroke. See INCIDENCE and PERCUSSION.

REFLECTION *of the Rays of Light*, like that of other bodies, is their motion after being reflected from the surfaces of bodies. The reflection of the rays of light from the surfaces of bodies, is the means by which those bodies become visible. And the disposition of bodies to reflect this or that kind of rays most copiously, is the cause of their being of this or that colour. Also, the reflection of light, from the surfaces of mirrors, makes the subject of catoptrics.

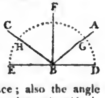
The reflection of light, Newton has shown, is not effected by the rays striking on the very parts of the bodies;

but by some power of the body equally diffused throughout its whole surface, by which it acts upon the ray, attracting or repelling it without any real immediate contact. This power he also shows is the same by which, in other circumstances, the rays are refracted; and by which they are at first emitted from the lucid body.

Dr. Priestley says, it is not more probable, that the rays of light are transmitted from the sun, with an uniform disposition to be reflected or refracted, according to the circumstances of the bodies on which they impinge; and that the transmission of some of the rays, apparently under the same circumstances, with others that are reflected; is owing to the minute vibrations of the small parts of the surfaces of the mediums through which the rays pass; vibrations that are independent of action and reaction between the bodies and the particles of light at the time of their impingeing, though probably excited by the action of preceding rays. Hist. of Light and Colours, pa.309.

Newton concludes his account of the reflection of light with observing, that if light be reflected not by impingeing on the solid parts of bodies, but by some other principle, it is probable that as many of its rays as impinge on the solid parts of bodies are not reflected, but stifled and lost in the bodies. Otherwise, he says, we must suppose two kinds of reflection; for should all the rays be reflected which impinge on the internal parts of clear water or crystal, those substances would rather have a cloudy colour, than a clear transparency. To make bodies look black, it is necessary that many rays be stopped, retained and lost in them; and it does not seem probable that any rays can be stopped and stifled in them, which do not impinge on their parts: and hence, he says, we may understand, that bodies are much more rare and porous than is commonly believed. However, M. Bouguer disputes the fact of light being stifled or lost by impingeing on the solid parts of bodies.

Reflection, in Catoptrics, is the return of a ray of light from the polished surface of a speculum or mirror, as driven thence by some power residing in it. The ray thus returned is called a reflex or reflected ray, or a ray of reflection; and the point of the speculum where the ray commences, is called the point of reflection. Thus, the ray AB, proceeding from the radiant A, and striking on the point of the speculum B, being returned thence to C, BC represents the reflected ray, and B the point of reflection; in respect of which, AB represents the incident ray, or ray of incidence, and B the point of incidence; also the angle CBE is the angle of reflection, and ABD the angle of incidence; where DE is the reflecting surface, or at least a tangent to it at the point B. Though some count the angle of incidence and of reflection from the perpendicular BF.



General Laws of Reflection.—1. When a ray of light is reflected from a speculum of any form, the angle of incidence is always equal to the angle of reflection. This law obtains in the percussions of all kinds of bodies; and consequently must do so in those of light; the proof of which may be seen at the article Incidence. This law is confirmed also by experiments on all bodies: and on the rays of light in this manner: A ray from the sun falling on a mirror, in a dark room, through a small hole, will be seen to rebound, so as to make the angle of reflection equal to the angle of incidence. And the same may be shown in various other ways: thus ex. gr. placing a semicircle DFE on a mirror DE, its centre on B, and its limb or plane perpendicular to the speculum; then assuming equal arcs DG and EH; place an object in A, and the eye in C: then will the object be seen by a ray reflected from the point B. But by covering B, the object will cease to be seen.

II. Every point of a speculum reflects rays falling on it, from every point of an object.

III. If the eye C and the radiant point A change places, the point will continue to radiate upon the eye, in the same course or path as before.

IV. The plane of reflection is perpendicular to the surface of the speculum; and it passes through the centre in spherical specula.

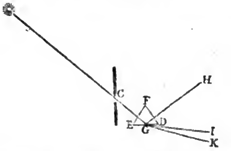
Reflection *of the Moon*, is a term used by some authors for what is otherwise called her variation; being the 3d inequality in her motion, by which her true place out of the quadratures differs from her place twice equated.

Reflection is also used in the Copernican system, for the distance of the pole from the horizon of the disc; which is the same thing as the sun's declination in the Ptolemaic system.

REFLECTOIRE Curve. See *Reflectoire* Curve.

REFLEXIBILITY *of the Rays of Light*, is that property by which they are disposed to be reflected. Or, it is their disposition to be turned back into the same medium, from any other medium on whose surface they fall. Hence those rays are said to be more or less reflexible, which are returned back more or less easily under the same incidence. Thus, if light pass out of glass into air, and by being inclined more and more to the common surface of the glass and air, begins at length to be totally reflected by that surface, those kinds of rays which at like incidences are reflected most copiously, or the rays which by being inclined begin soonest to be totally reflected, are the most reflexible rays.

That rays of light are of different colours, and endued with different degrees of reflexibility, was first discovered by sir I. Newton; and it is shown by the following experiment. Applying a prism DFE to the aperture C of a



darkened room, in such manner that the light be reflected from the base in G; the violet rays are seen first reflected into HG; the other rays continuing still refracted to I and K. After the violet, the blue are all reflected; then the green, &c.—Hence it appears, that the differently coloured rays differ in degree of reflexibility. And from other experiments it appears, that those rays which are most reflexible, are also most refrangible.

REFLUX *of the Sea*, is the ebbing of the water, or its return from the shore; being so called, because it is the opposite motion to the flood or flux. See Tide.

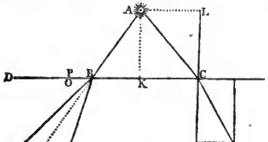
REFRACTED *Angle*, or *Angle of Refraction*, in Optics, is the angle which the refracted ray makes with the refracting surface; or sometimes it denotes the complement of that, or the angle it makes with the perpendicular to the said surface.

REFRACTED *Dials*, or *Refracting Dials*, are such as show the hour by means of some refracting transparent fluid.

REFRACTED *Ray*, or *Ray of* REFRACTION, is a ray after it is broken or bent, at the common surface of two different mediums, where it passes from the one into the other. See RAY, and REFRACTION.

REFRACTING *Telescope*, is one by which the rays from an object are transmitted to the eye through certain lenses of a proper form. See TELESCOPE.

REFRACTION, in Mechanics, is the deviation of a moving body from its direct course, by reason of the different density of the medium it moves in; or a flexion and change of determination, occasioned by a body's passing obliquely out of one medium into another of a different density.



Thus, a ball A, moving in the air in the line AB, and falling obliquely on the surface of the water CD, does not proceed straight in the same direction, as to E, but deviates or is deflected to F. Again, if the ball move in water in the line AB, and fall obliquely on a surface of air CD, it will in this case also deviate from the same continued direction BE, but the contrary way, and will go to G, on the other side of it. Now the deflection in either case is called the Refraction, the refraction being towards the denser surface BD in the former case, but from it in the latter.

These refractions are supposed to arise from hence; that the ball arriving at B, in the first case finds more resistance or opposition on the one side O, or from the side of the water, than it did from the side P, or that of the air; and in the latter more resistance from the side P, which is now the side of the water, than the side O, which is that of the air. And so for any other different media: a visible instance of which is often perceived in the falling of shot or shells into the earth, as clay &c, when the perforation is found to rise a little upwards, toward the surface. However, another reason is assigned for the refraction of the rays of light, whose refractions lie the contrary way to those above, as will be seen in what follows, viz, that water by its greater attraction accelerates the motion of the rays of light more than air does.

REFRACTION *of Light*, in Optics, is an inflection or deviation of the rays from their rectilinear course on passing obliquely out of one medium into another, of a different density. That a body may be refracted, it is necessary that it should fall obliquely on the second medium: in perpendicular incidence there is no refraction. Yet Voscius and Snell imagined they had observed a perpendicular ray of light undergo a refraction; a perpendicular object appearing in the water nearer than it really was: but this was attributing that to a refraction of the perpendicular rays, which was owing to the divergency of the oblique rays after refraction, from a nearer point. Yet there is a manifest refraction even of perpendicular rays found in island crystal.

Rohault adds, that though an oblique incidence be necessary in all other mediums we know of, yet the obliquity must not exceed a certain degree; if it do, the body will not penetrate the medium, but will be reflected, instead of being refracted. Thus, cannon-balls, in sea engagements, falling very obliquely on the surface of the water, are observed to bound or rise from it, and to sweep the men from off the enemy's decks. And the same thing happens to the little stones with which children make their ducks and drakes along the surface of the water.—The ancients confounded refraction with reflection; and it was Newton who first taught the true difference between them. He shows however that there is a good deal of analogy between them, and particularly in the case of light.

The laws of refraction of the rays of light in mediums differently terminated, i. e. whose surfaces are plane, concave, and convex, make the subject of Dioptrics. By refraction it is, that convex glasses, or lenses, collect the rays, magnify objects, burn, &c; and hence the foundation of microscopes, telescopes, &c.—And by refraction it is, that all remote objects are seen out of their real places; particularly, that the heavenly bodies are apparently higher than they are in reality. The refraction of the air has many times so uncertain an influence on the places of celestial objects, near the horizon, that wherever refraction is concerned, the conclusions deduced from observations that are much affected by it, will always remain doubtful, and sometimes too precarious to be relied on. See Dr. Bradley in Philos. Trans. number 485.

As to the cause of refraction, it does not appear that any person before Descartes attempted to explain it: this he undertook to do by the resolution of forces, on the principles of mechanics; in consequence of which, he was obliged to suppose that light passes with more ease through a dense medium than a rare one; thus, the ray AC falling obliquely on a denser medium at C is supposed to be acted on by two forces, one of them impelling it in the direction AI, and the other in AK, which alone can be effected by the change of medium; and since, after the ray has entered the denser medium, it approaches the perpendicular CI, it is plain that this force must have received an increase, while the other continued the same.

The first person who questioned the truth of this explanation of the cause of refraction, was Fermat: he asserted, contrary to Descartes, that light suffers greater resistance in water than in air, and greater in glass than in water; and he maintained that the resistance of different mediums, with respect to light, is in proportion to their densities. Leibnitz also adopted the same general idea; and they reasoned on the subject in the following manner. Nature, say they, accomplishes her ends by the shortest methods; and therefore light ought to pass from one point to another, either by the shortest course, or by that in which the least time is required. But it is plain that the path in which light passes, when it falls obliquely on a denser medium, is not the most direct or the shortest; and therefore it must be that in which the least time is spent. And whereas it is demonstrable, that light falling obliquely upon a denser medium (in order to take up the least time possible, in passing from a point in one medium to a point in the other) must be refracted in such a manner, that the sine of the angles of incidence and refraction must be to one another, as the different facilities with which light is transmitted in those mediums; it follows that, since light approaches the perpendicular when it passes obliquely from air into water, the facility with which water suffers light to pass through it, is less than that of the air; so that the light meets with greater resistance in water than in air.

This method of arguing from final causes could not satisfy philosophers. Dr. Smith observes, that it agrees only to the case of refraction at a plane surface; and that the hypothesis is altogether arbitrary.

Dechales, in explaining the law of refraction, supposes that every ray of light is composed of several smaller rays, which adhere to one another; and that they are refracted towards the perpendicular, in passing into a denser medium, because one part of the ray meets with more resistance than another part; so that the former traverses a smaller space than the latter; in consequence of which the ray must necessarily bend a little towards the perpendicular. This hypothesis was adopted by the celebrated Dr. Barrow, and indeed some say, he was the author of it. Now on this hypothesis it is plain, that mediums of a greater refractive power, must give a greater resistance to the passage of the rays of light, than mediums of a less refractive power; which is contrary to fact.

The Bernoullis, both father and son, have attempted to explain the cause of refraction on mechanical principles; the former on the equilibrium of forces, and the latter on the same principles with the supposition of ethereal vortices: but neither of these hypotheses has gained much credit.

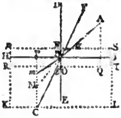
M. Mairan supposes a subtle fluid, filling the pores of all bodies, and extending, like an atmosphere, to a small distance beyond their surfaces; and then he supposes that the refraction of light is nothing more than a necessary and mechanical effect of the incidence of a small body in those circumstances. There is more, he says, of the refracting fluid, in water than in air, more in glass than in water, and in general more in a dense medium than in one that is rarer.

Maupertuis supposes that the course which every ray takes, in passing out of one medium into another, is that which requires the least quantity of action, which depends on the velocity of the body and the space it passes over; so that it is in proportion to the sum of the products arising from the spaces multiplied by the velocities with which bodies pass over them. From this principle he deduces the necessity of the sine of the angle of incidence being in a constant ratio to that of refraction; and also all the other laws relating to the propagation and reflection of light.

Dr. Smith (in his Optics, Remarks, p. 70) observes, that all other theories for explaining the reflexion and refraction of light, except that of Newton, suppose that it strikes upon bodies and is resisted by them; which has never been proved by any deduction from experience. On the contrary, it appears from various considerations, and might be shown by the observations of Mr. Molyneux and Dr. Bradley on the parallax of the fixed stars, that their rays are not at all impeded by the rapid motion of the earth's atmosphere, nor by the object-glass of the telescope, through which they pass. And by Newton's theory of refraction, which is grounded on experience only, it appears that light is so far from being resisted and retarded by refraction into any dense medium, that it is swifter there than in vacuo in the ratio of the sine of incidence in vacuo to the sine of refraction into the dense medium. Priestley's Hist. of Light, &c, p. 102 and 333.

Newton shows that the refraction of light is not performed by the rays falling on the very surface of bodies; but that it is effected, without any contact, by the action of some power belonging to bodies, and extending to a certain distance beyond their surfaces; by which same power, acting in other circumstances, they are also emitted and reflected.

The manner in which refraction is performed by mere attraction, without contact, may be thus accounted for: Now suppose HI the boundary of two mediums, N and O; the first the rarer, ex. gr. air; the second the denser, ex. gr. glass; the attraction of the mediums here will be as their densities. Suppose *ps* to be the distance to which the attracting force of the denser medium exerts itself within the rarer. And let a ray of light A*a* fall obliquely on the surface which separates the mediums, or rather on the surface *ps*, where the action of the second and more resisting medium commences; then as the ray arrives at *a*, it will begin to be turned out of its rectilinear course by a superior force, with which it is attracted by the medium O, more than by the medium N; hence the ray is bent out of its right line in every point of its passage between *ps* and RT, within which distance the attraction acts; and therefore between these lines it describes a curve *aBb*; but beyond RT, being out of the sphere of attraction of the medium N, it will proceed uniformly in a right line, according to the direction of the curve in the point *b*.



Again, suppose N the denser and more attracting medium, O the rarer, and HI the boundary as before; and let RT be the distance to which the denser medium exerts its attractive force within the rarer: then even when the ray has passed the point B, it will be within the sphere of the superior attraction of the denser medium; but that attraction acting in lines perpendicular to its surface, the ray will be continually drawn from its straight course BM perpendicularly towards HI: thus, having two forces or directions, it will have a compound motion, by which, instead of BM, it will describe B*m*, which will in strictness be a curve. Lastly, after it has arrived at *m*, being out of the influence of the medium N, it will persist uniformly, in a right line, in the direction in which the extremity of the curve leaves it.—Thus we see how refraction is performed, both towards the perpendicular DE, and from it.

REFRACTION *in Dioptrics*, is the inflexion or bending of the rays of light, in passing the surfaces of glasses, lenses, and other transparent bodies of different densities. Thus, a ray, as AB, falling obliquely from the radiant A, upon a point B, in a diaphanous surface HI, rarer or denser than the medium along which it was propagated from the radiant, has its direction there altered by the action of the new medium; and instead of proceeding to M, it deviates, as for ex. to C.

This deviation is called the Refraction of the ray; BC the Refracted ray, or Line of Refraction; and B the Point of Refraction.—The line AB is also called the Line of Incidence; and in respect of it, B is also called the Point of Incidence. The plane in which both the incident and refracted ray are found, is called the Plane of Refraction; also a right line BE drawn in the refracting medium perpendicular to the refracting surface at the point of refraction B, is called the Axis of Refraction; and its continuation DB along the medium through which the ray falls, is called the Axis of Incidence.—Further, the angle ABI, made by the incident ray and the refracting surface, is usually called the Angle of Incidence; and the angle ABD, between the incident ray and the axis of incidence, is the Angle of Inclination. Moreover, the angle MBC, between the refracted and incident rays, is called the Angle of Refraction; and the angle CBE, between the refracted ray and the axis of refraction, is the Refracted Angle. But it is also very common to call the angles ABD and CBE, made by the perpendicular with the incident and refracted rays, the Angles of Incidence and Refraction.

General Laws of REFRACTION.—I. A ray of light in its passage out of a rarer medium into a denser, ex. gr. out of air into water or into glass, is refracted towards the perpendicular, i. e. towards the axis of refraction. Hence, the refracted angle is less than the angle of inclination; and the angle of refraction less than that of incidence; as they would be equal were the ray to proceed straight from A to M.

II. The ratio of the sines of the angles ABD, CBE, made by the perpendicular with the incident and refracted rays, is a constant and fixed ratio; whatever be the obliquity of the incident ray, the mediums remaining. Thus, the refraction out of air into water, is nearly as 4 to 3, and into glass it is nearly as 3 to 2. As to air in particular, it is shown by Newton, that a ray of light, in traversing quite through the atmosphere, is refracted the same as it would be, were it to pass with the same obliquity out of a vacuum immediately into air of equal density with that in the lowest part of the atmosphere.

It appears, from Ptolemy's Optics, that he was well acquainted with the phenomena of the refraction of light, in passing from one medium to another; but he knew neither the law nor the exact quantity of it, though he made some experiments on it. Vitello, who collected the knowledge of the ancients on this subject, and their experiments, gave a false law for the comparison of the effect, erroneously stating that the angles of incidence and reflexion are always in a constant ratio.

The true law of refraction was first discovered by Willebrord Snell, professor of mathematics at Leyden; who found by experiment that the cosecants of the angles of incidence and refraction are always in the same ratio. It was commonly attributed however to Descartes; who, having seen it in a MS. of Snell's, first published it in his Dioptrics, without naming Snell, as Huygens asserts; Descartes having only altered the form of the law, from the ratio of the cosecants, to that of the sines, which is the same thing.

It is to be observed however, that as the rays of light are not all of the same degree of refrangibility, this constant ratio must be different in different kinds: so that the ratio mentioned by authors, is to be understood of rays of the mean refrangibility, i. e. of green rays. The difference of refraction between the least and most refrangible rays, that is, between violet and red rays, Newton shows, is about the $\frac{2}{27}$ of the whole refraction of the mean refrangible; which difference, he allows, is so small, that it seldom needs to be regarded.

Different transparent substances have indeed very different degrees of refraction, and those not according to any regular law; as appears by many experiments of Newton, Euler, Hawksbee, &c. See Newton's Optics, 3d edit. pa. 247; Hawksbee's Experim. pa. 292; Act. Berlin. 1762, pa. 302; Priestley's Hist. of Light &c, pa. 479.

Whence the different refractive powers in different fluids arise, has not been determined. Newton shows, that in many bodies, as glass, crystal, selenites, pseudo-topaz, &c, the refractive power is indeed proportionable to their densities; while in sulphureous bodies, as camphor, linseed, and olive oil, amber, spirit of turpentine, &c, the power is 2 or 3 times greater than in other bodies of equal density; and yet even these have the refractive power with respect to each other, nearly as their densities. Water has a refractive power in a medium degree between those two kinds of substances; while salts and vitriols have refractive powers in a middle degree between those of earthy substances and water, and accordingly are composed of those two kinds of matter. Spirit of wine has a refractive power in a middle degree between those of water and oily substances; and accordingly it seems to be composed of both, united by fermentation. It appears therefore, that all bodies seem to have their refractive powers nearly proportional to their densities, excepting so far as they partake more or less of sulphureous oily particles, by which those powers are altered.

Newton suspected that different degrees of heat might have some effect on the refractive power of bodies; but his method of determining the general refraction was not sufficiently accurate to ascertain this circumstance. Euler's method however was well adapted to this purpose: and from his experiments he infers, that the focal distance of a single lens of glass diminishes with the heat communicated to it; which diminution is owing to a change in the refractive power of the glass itself, which is probably increased by heat, and diminished by cold, as well as that of all other translucent substances.

From the law above laid down it follows, that one angle of inclination, and its corresponding refracted angle, being found by observation, the refracted angles corresponding to the several other angles of inclination are thence easily computed. Now, Zahnius and Kircher have found, that if the angle of inclination be 70°, the refracted angle, out of air into glass, will be 38° 50′; on which principle Zahnius has constructed a table of those refractions for the several degrees of the angle of inclination; a specimen of which here follows:

Angle of Inclination.	Refracted Angle.			Angle of Refraction.		
1°	0°	40′	5″	0°	19′	55″
2	1	20	6	0	39	54
3	2	0	4	0	59	56
4	2	40	5	1	19	55
5	3	20	3	1	39	57
10	6	39	16	3	20	44
20	13	11	35	6	48	25
30	19	29	29	10	30	31
45	28	9	19	16	50	41
90	41	51	40	48	8	20

Hence it appears, that if the angle of inclination be less than 20°, the angle of refraction out of air into glass is almost ⅓ of the angle of inclination; and therefore a ray is refracted to the axis of refraction by almost a third part of the quantity of its angle of inclination. And on this principle it is that Kepler, and most other dioptrical writers, demonstrate the refractions in glasses; though in estimating the law of these refractions he followed the example of Albazen and Vitello, and sought to discover it in the proportion of the angles, and not in that of the sines, or cosecants, as discovered by Snell.

The refractive powers of several substances, as determined by different philosophers, may be seen in the following tables; in which the ray is supposed to pass out of air into each of the substances, and the annexed numbers show the ratio to unity or 1, between the sines of the angles of incidence and refraction.

III. When a ray passes out of a denser medium into a rarer, it is refracted from the perpendicular, or from the axis of refraction.

This is exactly the reverse of the 2d law, and the quantity of refraction is equal in both cases, or both forwards and backwards; so that a ray would take the same course back, by which another passed forward, viz, if a ray were to pass from A by B to C, another would pass from C by B to A. Hence, in this case, the angle of refraction is greater than the angle of inclination. And also, if the angle of inclination be less than 30°, MBC is nearly equal to ⅓ of MBE; therefore MBC is ½ of CBE; consequently, if the refraction be out of glass into air, and the angle of inclination less than 30°, the ray is refracted from the axis of refraction by almost the half of the angle of inclination. And this is the other dioptrical principle used by most authors after Kepler, to demonstrate the refractions of glasses.

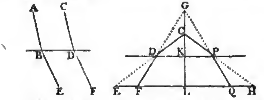
If the refraction be out of air into glass, the ratio of the sines of inclination and refraction is as 3 to 2, or more accurately as 17 to 11; if out of air into water as 4 to 3; therefore if the course be the contrary way, viz, out of glass or water into air, the ratio of the sines will be, in the former case as 2 to 3 or 11 to 17, and in the latter as 3 to 4. So that, if the refraction be from water or glass into air, and the angle of incidence or inclination be greater than about 48½ degrees in water, or greater than about 40° in glass, the ray will not be refracted into air; but will be reflected into a line which makes the angle of reflection equal to the angle of incidence; because the sines of 48½ and 40° are to the radius, as 3 to 4, and as 11 to 17 nearly; and therefore, when the sine has a greater proportion to the radius than as above, the ray will not be refracted.

IV. A ray falling on a curve surface, whether concave or convex, is refracted after the same manner as if it fell on a plane which is a tangent to the curve in the point of incidence. Because the curve and its tangent have the point of contact common to both, where the ray is refracted.

Laws of REFRACTION *in Plane Surfaces.*

1. If parallel rays, AB and CD, be refracted out of one transparent medium into another of a different density,

they will continue parallel after refraction, as BE and DF. Hence a glass that is plane on both sides, being turned either directly or obliquely to the sun, &c, the light passing through it will be propagated in the same manner as if the glass were away.

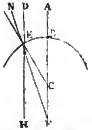


2. If two rays CD and CP, proceeding from the same radiant C, and falling on a plane surface of a different density so that the points of refraction D and P be equally distant from the perpendicular of incidence GK, the refracted rays DF and PQ have the same virtual focus, or the same point of dispersion G.—Hence, when refracted rays, falling on the eye placed out of the perpendicular of incidence, are either equally distant from the perpendicular, or very near each other, they will flow upon the eye as if they came to it from the point G; consequently the point C will be seen by the refracted rays as in G. And hence also, if the eye be placed in a dense medium, objects in a rarer will appear more remote than they are; and the place of the image, in any case, may be determined from the ratio of refraction: Thus, to fishes swimming under water, objects out of the water must appear farther distant than in reality they are. But on the contrary, if the eye at E be placed in a rarer medium, then an object G placed in a denser, appears, at C, nearer than it is; and the place of the image may be determined in any given case by the ratio of refraction; and thus the bottom of a vessel full of water is raised by refraction a third part of its depth, with respect to an eye placed perpendicularly over the refracting surface; and thus also fishes and other bodies, under water, appear nearer than they really are.

3. If the eye be placed in a rarer medium; then an object seen in a denser, by a ray refracted in a plane surface, will appear larger than it really is. But if the eye be in a denser medium, and the object in a rarer, the object will appear less than it is. And in each case, the apparent magnitude FQ is to the real one EH, as the rectangle CK.GL to GK.CL, or in the compound ratio of the distance CK of the point to which the rays tend before refraction, from the refracting surface DP, to the distance GK of the eye from the same, and of the distance GL of the object EH from the eye, to its distance CL from the point to which the rays tend before refraction.—Hence, if the object be very remote, CL will be physically equal to GL; and then the real magnitude EL is to the apparent magnitude FL, as GK to CK, or as the distance of the eye G from the refracting plane, to the distance of the point of convergence F from the same plane. And hence also, objects under water, to an eye in the air, appear larger than they are; and to fishes under water, objects in the air appear less than they are.

Laws of REFRACTION *in Spherical Surfaces, both concave and convex.*

1. A ray of light DE, parallel to the axis, after a single refraction at E, meets the axis in the point F, beyond the centre C.



2. Also in that case, the semidiameter CB or CE will be to the refracted ray EF, as the sine of the angle of refraction to the sine of the angle of inclination BCE. But the distance of the focus, or point of concurrence from the centre, CF, is to the refracted ray EF, as the sine of the refracted angle to the sine of the angle of inclination.

3. Hence also, in this case, the distance BF of the focus from the refracting surface, must be to CF its distance from the centre, in a ratio greater than that of the sine of the angle of inclination to the sine of the refracted angle. But those ratios will be nearly equal when the rays are very near the axis, and the angle of inclination BCE is only of a few degrees. And when the refraction is out of air into glass, then

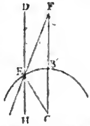
For rays near the axis,	For more distant rays,
BF : FC : : 3 : 2,	BF : FC > 3 : 2,
BC : BF : : 1 : 3.	BC : BF < 1 : 3.

But if the refraction be out of air into water, then

For rays near the axis,	For more distant rays,
BF : FC : : 4 : 3,	BF : FC > 4 : 3,
BC : BF : : 1 : 4.	BC : BF < 1 : 4.

Hence, as the sun's rays are parallel as to sense, if they fall on the surface of a solid glass sphere, or of a sphere full of water, they will not meet the axis within the sphere: so that Vitello was mistaken when he imagined that the sun's rays, falling on the surface of a crystalline sphere, were refracted to the centre.

4. If a ray HE fall parallel to the axis FA, out of a rarer medium, on the concave spherical surface BE of a denser one; the refracted ray EN will diverge from the point of the axis F, so that FE will be to FC, in the ratio of the sine of the angle of inclination, to the sine of the refracted angle. Consequently FB to FC is in a greater ratio than that; unless when the rays are very near the axis, and the angle BCE is very small, for then FB will be to FC nearly in that ratio. And hence, in the cases of refraction out of air into water or glass, the ratios of BC, BF and CF, will be the same as specified in the last article.



5. If a ray DE, parallel to the axis FC, pass out of a denser into a rarer spherical convex medium, it will diverge from the axis after refraction; and the distance FC of the point of dispersion, or of the virtual focus F, from the centre of the sphere, will be to its semidiameter CE or CB, as the sine of the refracted angle is to the sine of the angle of refraction; but to the portion of the refracted ray drawn back, FE, it will be in the ratio of the sine of the refracted angle to the sine of the angle of inclination. Consequently FC will be to FB, in a greater ratio than this last: unless when the rays DE fall very near the axis FC, for then FC to FB will be very nearly in that ratio.

Hence, when refraction is out of glass into air; then,

For rays near the axis,	For more distant rays,
FC : FB : : 3 : 2,	FC : FB > 3 : 2,
BC : BF : : 1 : 2.	BC : BF > 1 : 2.

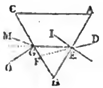
But when the refraction is out of water into air; then,

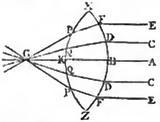
For rays near the axis,	For more distant rays,
FC : FB : : 4 : 3,	FC : FB > 4 : 3,
BC : BF : : 1 : 3.	BC : BF > 1 : 3.

6. If the ray HE fall parallel to the axis CF, from a denser medium, upon the surface of a spherically concave rarer one; the refracted ray will meet with the axis in the point F, so that the distance CF from the centre, will be to the refracted ray FE, as the sine of the refracted angle, to the sine of the angle of inclination. Consequently FC will be to FB, in a greater ratio than that above mentioned: unless when the rays are very near the axis, for then FC is to FB very nearly in that ratio; and the three FB, FC, BC are, in the cases of air, water, and glass, in the numeral ratios as specified at the end of the last article. See Wolfius, Elem. Mathes. tom. 3, pa. 179 &c.

REFRACTION *in a Glass Prism*.

ABC being the transverse section of a prism; if a ray of light DE fall obliquely upon it out of the air; instead of proceeding straight on to F, being refracted towards the





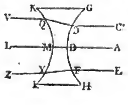
perpendicular IE, it will decline to O. Again, since the ray EG, passing out of glass into air, falls obliquely on BC, it will be refracted to M, so as to recede from the perpendicular GO. And hence arise the various phenomena of the prism. See COLOUR.

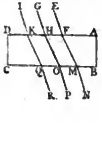
REFRACTION *in a Convex Lens*.

If parallel rays, AB, CD, EF, fall on the surface of a convex lens XBZ (the last fig. above); the perpendicular ray AB will pass unrefracted to K, where emerging, as before, perpendicularly, into air, it will proceed straight on to G. But the rays CD and EF, falling obliquely out of air into glass, at D and F, will be refracted towards the axis of refraction, or towards the perpendiculars at D and F, and so decline to Q and P: where emerging again obliquely out of the glass into the surface of the air, they will be refracted from the perpendicular, and proceed in the directions QG and PG, meeting in G. And thus also will all the other rays be refracted so as to meet the rest near the place G. See FOCUS and LENS.—Hence the great property of convex glasses; viz, that they collect parallel rays, or make them converge into a point.

REFRACTION *in a Concave Lens*.

Parallel rays AB, CD, EF, falling on a concave lens GBHIMK, the ray AB falling perpendicularly on the glass at B, will pass unrefracted to M; where, being still perpendicular, it will pass into the air to L, without refraction. But the ray CD, falling obliquely on the surface of





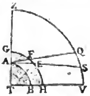
the glass, will be refracted towards the perpendicular at D, and proceed to Q; where again falling obliquely out of the glass upon the surface of air, it will be refracted from the perpendicular at Q, and proceed to V. After the same manner the ray EF is first refracted to Y, and thence to Z. —Hence the great property of concave glasses; viz, that they disperse parallel rays, or make them diverge. See LENS.

REFRACTION *in a Plane Glass*.

If parallel rays EF, GH, IK, (the last fig. above) fall obliquely on a plane glass ABCD; the obliquity being the same in all, by reason of their parallelism, they will be all equally refracted towards the perpendicular; and accordingly, being still parallel at M, O, and Q, they will pass out into the air equally refracted again from the perpendicular, and still parallel. Thus will the rays EF, GH, and IK, at their entering the glass, be inflected towards the right; and in their going out as much inflected to the left; so that the first refraction is here undone by the second, thereby causing the rays on their emerging from the glass, to be parallel to their first direction before they entered it; though not so as that the object is seen in its true place; for the ray KQ, being produced back again, will not coincide with the ray IK, but will fall to the right of it; and this the more as the glass is thicker; however, as to the colour, the second refraction does really destroy the first. See COLOUR.

REFRACTION *in Astronomy*, or REFRACTION *of the Stars*, is an inflexion of the rays of those luminaries, in passing through our atmosphere; by which the apparent altitudes of the heavenly bodies are increased. This refraction arises from hence, that the atmosphere is unequally dense in different stages or regions; rarest of all at the top, and densest of all at the bottom; which inequality in the same medium, makes it equivalent to several unequal mediums, by which the course of the ray of light is continually bent into a continued curve line. See ATMOSPHERE.—And Sir Isaac Newton has shown, that a ray of light, in passing from the highest and rarest part of the atmosphere, down to the lowest and densest, undergoes the same quantity of refraction that it would do in passing immediately, at the same obliquity, out of a vacuum into air of equal density with that in the lowest part of the atmosphere.

The effect of this refraction may be thus conceived. Suppose ZV a quadrant of a vertical circle described from the centre of the earth T, under which is AB a quadrant of a circle on the surface of the earth, and GH a quadrant of the surface of the atmosphere. Then suppose SE a ray of light emitted by a star at S, and falling on the atmosphere at E: this ray coming out of the ethereal medium, which is much rarer than our air, or perhaps out of a perfect vacuum, and falling on the surface of the atmosphere, will be refracted towards the perpendicular, or inclined down more towards the earth; and since the upper strata of air are rarer than those near the earth, and becomes still denser as they approach the earth's surface, the ray in its progress will be continually refracted, so as to arrive at the eye in the curve line EA. Then supposing the right line AF to be a tangent to the arch at A, the ray will enter the eye at A in the direction of AF; and therefore the star will appear in the heavens at Q, instead of S, higher or nearer the zenith than it really is.—



Hence arise the phenomena of the crepusculum or twilight; and hence also it is that the moon is sometimes seen eclipsed, when she is really below the horizon, and the sun above it.

That there is a real refraction of the stars &c, is deduced not only from physical considerations, and from arguments a priori, and a similitudine, but also from precise astronomical observation: for there are numberless observations by which it appears that the sun, moon, and stars rise much sooner, and appear higher, than they should do according to astronomical calculations. Hence it is argued, that as light is propagated in right lines, no rays could reach the eye from a luminary below the horizon, unless they were deflected out of their course, at their entrance into the atmosphere: and therefore it appears that the rays are refracted in passing through the atmosphere.

Hence the stars appear higher by refraction than they really are; so that to bring the observed or apparent altitudes to the true ones, the quantity of refraction must be subtracted. And hence, some of the ancients, as they were not acquainted with this refraction, reckoned their altitudes too great, so that it is no wonder they sometimes committed considerable errors. Hence also, refraction lengthens the day, and shortens the night, by making the sun appear above the horizon a little before his rising, and a little after his setting. Refraction also makes the moon and stars appear to rise sooner and set later than they really do. The apparent diameter of the sun or moon is about 32′; the horizontal refraction is about 33′; whence the sun and moon appear wholly above the horizon when they are entirely below it. Also, from observations it appears that the refractions are greater nearer the pole than at lesser latitudes, which causes the sun to appear some days above the horizon, when he is really below it; doubtless from the greater density of the atmosphere, and the greater obliquity of the incidence.

Stars in the zenith are not subject to any refraction; and those in the horizon have the greatest of all; the refraction continually decreasing from thence to the zenith. All which follows from hence, that in the first case, the rays are perpendicular to the medium; in the second, their obliquity is the greatest, and they pass through the largest space of the lower and denser part of the air, and through the thickest vapours; and in the third, the obliquity is continually decreasing.

The air is condensed, and consequently refraction is increased, by cold; for which reason it is greater in cold countries than in hot ones. It is also greater in cold weather than in hot, in the same country; and the morning refraction is greater than that of the evening, because the air is rarefied by the heat of the sun in the day, and condensed by the coldness of the night. Refraction is also subject to some small variation at the same time of the day in the finest weather.
